ON THE FLOW-LEVEL STABILITY OF DATA NETWORKS WITHOUT CONGESTION CONTROL: THE CASE OF LINEAR NETWORKS AND UPSTREAM TREES

MATHIEU FEUILLET

Abstract. In this paper, flow models of networks without congestion control are considered. Users generate data transfers according to some Poisson processes and transmit corresponding packet at a fixed rate equal to their access rate until the entire document is received at the destination; some erasure codes are used to make the transmission robust to packet losses. We study the stability of the stochastic process representing the number of active flows in two particular cases: linear networks and upstream trees. For the case of linear networks, we notably use fluid limits and an interesting phenomenon of "time scale separation" occurs. Bounds on the stability region of linear networks are given. For the case of upstream trees, underlying monotonic properties are used. Finally, the asymptotic stability of those processes is analyzed when the access rate of the users decreases to 0. An appropriate scaling is introduced and used to prove that the stability region of those networks is asymptotically maximized.

1. Introduction

Most Internet traffic derives from the transfer of stored documents, corresponding to texts, music and movies. This traffic is elastic in the sense that the transmission rate varies depending on current network congestion. Each document transfer is a flow of packets whose rate is usually regulated by the Transmission Control Protocol (TCP). The rate is allowed to increase linearly until a packet loss is observed. The rate is then divided by two. These two mechanisms ensure that network bandwidth is shared approximately fairly between the varying number of flows in progress at any time. TCP also ensures that lost packets are retransmitted.

There is, however, no constraint on users to actually implement TCP algorithm and a more aggressive, greedy congestion control would be individually more profitable. Indeed, new, more aggressive versions of TCP are emerging to better exploit increasing link capacity [9, 13, 25]. Some have suggested that the packet retransmission function of TCP could be replaced by forward error correction in the form of source coding [20]. It consists in the use of erasure codes in order to encode files before sending them into the network. As a consequence, if the file has been divided in K packets, the destination is able to rebuild the data with $(1+\varepsilon)K$ packets. A typical class of erasure codes which is adapted to source coding are the *Digital fountains* [18]. The use of source coding enables the relaxation of control requirements and facilitates aggressive packet transmission policies.

If the congestion avoidance of TCP is no longer universally used, there is a danger that the Internet may again experience the congestion collapse observed in its early

---

Date: September 8, 2011.

days [19]. Packets dropped downstream and therefore retransmitted needlessly encumber upstream links, amplifying and spreading congestion. The consequence may be that the rate realized by concurrent flows is much less than the optimum (in terms of utility maximization) and may even tend to zero. The capacity of a network can be defined as the demand, flow arrival rate × mean flow size, that can be sustained. It depends on the way bandwidth is shared. It is important to understand what happens to capacity when the assumption that users compliantly implement TCP is relaxed. This is our objective in the present paper.

In this paper, we assume users are greedy and do not implement congestion control. They send data at the greatest possible rate determined by an external constraint that we assimilate to an access rate. Bandwidth sharing is determined by this behavior. We consider a flow-level model, as decribed in [16], where the bandwidth allocation changes instantly as new flows arrive or existing flows terminate. Tail dropping is interpreted in this model such that, at each link, the output rate of flows is proportional to their input rate to the link in question. This is consistent with the assumption that packets are all equally likely to be dropped. The drop rate is such that the overall output rate is bounded by the link capacity. Flows are categorized into classes defined by their route and their access rate. We assume flows arrive according to a Poisson process and have an exponentially distributed size. The stochastic process describing the number of flows in each class is a Markov process. We say that the network is stable when this process is recurrent positive and unstable otherwise.

To illustrate the realized bandwidth sharing without congestion control, consider the linear network depicted in Figure 2 with two links 1, 2 of capacity C_1 and C_2, respectively, n_0 class-0 flows going through links 1 and 2, n_1 class-1 flows going through link 1 and n_2 class-2 flows going through link 2. The access rate for class-k flows is denoted by a_k. The aggregate input rates of classes 0 and 1 at the first link are respectively n_0a_0 and n_1a_1 and the total input rate at link 1 is $R_1 = n_0a_0+n_1a_1$. If $R_1 > C_1$, then the first link is saturated and the aggregate output rates of classes 0 and 1 are respectively

$$\theta_0^1 = C_1 \frac{n_0a_0}{n_0a_0+n_1a_1} \quad \text{and} \quad \theta_1^1 = C_1 \frac{n_1a_1}{n_0a_0+n_1a_1}.$$

If $R_1 \le C_1$ then the first link is not saturated and $\theta_0^1 = n_0a_0$ and $\theta_1^1 = n_1a_1$. The aggregate input rate of class 0 at link 2 is θ_0^1 and the aggregate input rate of class 2 is n_2a_2. As above, we derive the respective aggregate output rates of class 0 and 2 after link 2:

$$\theta_0^2 = \theta_0^1 \min\left(1, \frac{C_2}{\theta_0^1 + n_2a_2}\right) \quad \text{and} \quad \theta_2^2 = n_2a_2 \min\left(1, \frac{C_2}{\theta_0^1 + n_2a_2}\right).$$

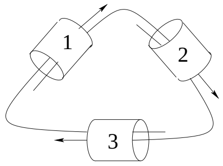

FIGURE 1. A cyclic network

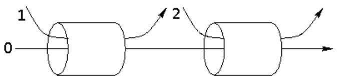

FIGURE 2. A linear network

The question of the capacity of networks without congestion control has already been addressed in [4]. It was shown that congestion collapse does occur in cyclic networks like that depicted in Figure 1 where the system is unstable for any positive demand. In acyclic networks, however, capacity is not reduced to 0 and this performance degradation is significantly mitigated by the access rates. It was conjectured in [4] that capacity in acyclic networks increases as access rates tend to 0 and, in the limit, is determined only by the optimal per-link stability conditions. In this paper, we prove that the conjecture is indeed true for two particular acyclic topologies, linear networks and upstream trees. For linear networks, we derive bounds on stability conditions for arbitrary access rates.

Averaging phenomenon. We evaluate stability conditions by applying fluid limit techniques. The end-to-end class in a linear network plays a particular role. In the fluid limit, all other flow classes are shown to empty in finite time for any initial conditions. When all these classes are empty, a phenomenon of *averaging* occurs and allow us to prove that the end-to-end class also empties in finite time. In that situation, the rate at which this class evolves depends on the stochastic evolution of the remaining local classes which in turn depends on the current fluid state of the end-to-end class. This dependence is decoupled by a time scale separation argument. The rate at which the fluid component (the end-to-end flow) evolves is infinitely slower than the rate at which the stochastic components evolve. It is therefore possible to apply a *quasi-stationary* model through which the *average* impact of the local traffic can be evaluated.

This is a non-trivial example of a local equilibrium of fluid limits. A simpler example of such a phenomenon can be found in [21, 9.6, p271]. Averaging in fluid limits has also been considered in the context of wireless networks (see [2] and subsequent papers [24] and [10]). The main difference here is that the local equilibrium depends on the state of the fluid limit. Note that this is somewhat related to the averaging phenomenon considered for loss networks [12].

To evaluate the impact of access rates on capacity, we introduce an ad-hoc scaling. Scaled processes are shown to converge to a simple deterministic process. Generally speaking, the convergence of processes does not imply the convergence of stationary distributions. However, in our case, we can prove this is true in two specific cases exhibiting an interesting example of limit inversion for stochastic processes. We use the same technique as in [7] to prove this inversion. We use the convergence of stationary distributions combined with the averaging phenomenon to prove the asymptotic optimality of linear networks. For upstream trees, we use convergence and monotonicity.

The paper is structured as follows. In Section 2, we give a complete description of the considered model. In Section 3, we study the stability conditions of linear networks with general access rates. In Section 4, we study the stability of linear networks and upstream trees when access rates decrease to 0 and prove their capacity is asymptotically optimal.

2. Flow-level model

2.1. **Bandwidth allocation.**

Consider a network of L links. Denote by C_l the capacity of link l. A number of flows compete to share the capacity of these links. The flows are categorized into a set of K classes. Each class-k flow has an access rate to the network denoted by a_k and follows a route of length d_k defined as an ordered set of distinct links $r_k = \{r_k(1), r_k(2), \ldots, r_k(d_k)\}$. Let $x = (x_1, \ldots, x_K)$ be the vector of input rates of all classes, $\psi_k(x)$ the aggregate throughput of class-k flows. We refer to the vector $\psi(x) = (\psi_1(x), \ldots, \psi_K(x))$ as the bandwidth allocation.

Here, we consider allocations that result when users are greedy and transmit at their maximum input rate in the network without any congestion control. There can be losses on each link of the network and we need to describe the evolution of the rate of each flow going through the network. Specifically, we assume that class-k flows initially transmit at full rate $\theta_k^0(x) = x_k = n_k a_k$ where n_k is the number of class-k active flows and we denote by $\theta_k^i(x)$ the class-k rate at the *output* of the i-th link on its route r_k, for $i = 1, 2, \ldots, d_k$. The actual throughput $\psi_k(x)$ of class k corresponds to the aggregate throughput of class-k flows at the output of the last link on their route, $\psi_k(x) = \theta_k^{d_k}(x)$. Due to potential loss at each link, we have

$$\psi_k(x) = \theta_k^{d_k}(x) \leq \theta_k^{d_k-1}(x) \leq \ldots \leq \theta_k^1(x) \leq \theta_k^0(x) = x_k = n_k a_k. \tag{1}$$

In particular, $\theta_k^{i-1}(x) - \theta_k^i(x)$ is the loss for class k occurring at the i-th link on its route.

The total rate at the output of each link cannot exceed the capacity of this link, so that

$$\forall l, \quad \sum_{k,i:r_k(i)=l} \theta_k^i(x) \leq C_l. \tag{2}$$

In order to characterize the allocation achieved in the absence of congestion control, it remains to determine how output rates depend on input rates at each link. This depends on the buffer management policy. In the considered fluid model, losses occur on saturated links only when the total input rate exceeds the capacity; the total output rate is then assumed to be equal to the capacity. In the following, we consider a single buffer management policy, Tail Dropping, which simply consists in dropping each incoming packet when the buffer is full. We deduce that, at the flow level, the output rate of classes from the link is proportional to the input rate of classes to the link.

Specifically, let $R_l(x)$ be the total input rate of link l:

$$R_l(x) = \sum_{k,i:r_k(i+1)=l} \theta_k^i(x).$$

If $R_l(x) \leq C_l$ then link l is not saturated and there are no losses; the output rate is equal to the input rate for each class. If $R_l(x) > C_l$, then the link is saturated and there are losses proportional to the input rate. The output rate of any class k then satisfies for all $i = 1, 2, 3, \ldots, d_k$,

$$\theta_k^i(x) = \theta_k^{i-1}(x) \min\left(\frac{C_l}{R_l(x)}, 1\right) \quad \text{where } l = r_k(i). \tag{3}$$

When there is no ambiguity and when the access rates are fixed, the bandwidth allocation is determined by the number of flows in each class. We denote by $n = (n_1, \ldots, n_K)$ the vector of the numbers of flows in progress and by the vector $\phi(n) = (\phi_1(n), \ldots, \phi_K(n))$ the bandwidth allocation where, for each k, $\phi_k(n) = \psi_k(a \odot n)$ where $\odot$ denote the componentwise product.

For example, we can consider a linear network under tail dropping (see Section 3) with two links of capacity 1 with access rates all equal to 1 and 1 flow in each class. We get the following bandwidth allocation:

$$\phi_0(1,1,1) = \frac{1}{3},\ \phi_1(1,1,1) = \frac{1}{2},\ \phi_2(1,1,1) = \frac{2}{3}.$$

It is not obvious that (3) defines a unique allocation for all networks. The definition is clearly non-ambiguous for *acyclic* networks, i.e., if links can be numbered in such a way that each route consists of an increasing sequence of link indexes. The allocation then directly follows from applying (3) to all $l = 1, \dots, L$, successively. For general networks, the allocation is still well-defined and unique as proved in [4]. In this paper, we consider only acyclic networks.

2.2. **Flow dynamics.** We assume that class-k flows are generated according to a Poisson process of intensity λ_k and have independent, exponentially distributed sizes with mean $1/\mu_k$. We define the traffic intensity of class-k flows as $\rho_k = \lambda_k/\mu_k$.

Under the above assumptions, let $N(t)$ denote the number of flows at time t, $(N(t), t \in \mathbb{R}_+)$ defines a Markov process with transition rates λ_k from state n to state $n + e_k$ and $\phi_k(n)\mu_k$ from state n to state $n - e_k$, where e_k denotes the vector with 1 in the k-th component and 0 elsewhere. We say that the network is *stable* when this Markov process is ergodic. There is a well-known necessary stability condition (see [3]) which is that the traffic intensity is less than the capacity for all links:

$$\forall l, \quad \sum_{k: l \in r_k} \rho_k < C_l. \tag{4}$$

An allocation will be called optimal if this condition is also sufficient. In the rest of this paper, this condition will be further referred to as the *optimal stability condition.*

In the following, we study stability conditions for two specific classes of networks. In Section 3, we consider linear networks. In Section 4, we study the behavior of stability conditions when the access rates are small for linear networks and upstream trees.

3. Stability conditions for a linear network

3.1. **Linear networks.** We consider a linear network with L links as depicted in Figure 2. For the sake of simplicity, we assume that the capacity of all links is 1 but all the results are true in the general case and can be obtained by adapting the notation. The linear network has $K = L + 1$ different classes of flows. Class-0 flows go through all links. We label the links of the network from 1 to L. Link l is the l-th link on the route of class-0 flows. Class-l flows go through link l only. Equation (3) can be rewritten as follows for a given state n and for $1 \le k \le L$:

$$\theta_0^k(x) = \min\left(\theta_0^{k-1}(x), \frac{\theta_0^{k-1}(x)}{\theta_0^{k-1}(x) + x_k}\right),$$

$$\theta_k^1(x) = \min\left(x_k, \frac{x_k}{\theta_0^{k-1}(x) + x_k}\right).$$

To simplify the presentation, we suppose that $a_0 = 1$ and $a_1 = 1$. In that case, a single flow of class 0 or 1 is enough to saturate the first link and we have

$$\theta_0^1(n \odot a) = \frac{n_0}{n_1 + n_0} \quad \text{and} \quad \theta_1^1(n \odot a) = \frac{n_1}{n_0 + n_1}.$$

All the results presented here remain true without this assumption. Only the proof of Proposition 6 has to be adapted.

In the rest of this section, we study the stability conditions of the stochastic process resulting from this linear network. The optimal stability conditions (4) are:

$$\rho_0 + \rho_k < 1 \text{ for } 1 \le k \le L. \tag{5}$$

3.2. **General fluid limits.** We show that classes $2, \dots, L$ are favored compared to classes 0 and 1 in the sense that the ergodicity conditions of classes $2, \dots, L$ do not depend on classes 0 and 1 but the contrary is not true.

In order to study the ergodicity of the system, we need to define fluid limits. In the following, we consider the norm such that for $x \in \mathbb{R}^K$, $\|x\| = \sum_{i=1}^K |x_i|$. Let $(m^i, i \in \mathbb{N})$ be a sequence of $\mathbb{N}^K$ such that $\lim_{i\to\infty} \|m^i\| = \infty$. Define for all $m \in \mathbb{N}^K$, the process $(N^m(t))$ describing the system evolution under tail dropping when starting at $N^m(0) = m$. A fluid limit $\bar{Z}$ of the system is defined as an accumulation point of the laws of the processes in the set

$$\mathcal{C} = \left\{ (N^{m^i}(\|m^i\|t)/\|m^i\|, t \ge 0), i \in \mathbb{N} \right\}$$

which is regarded as a subset of the space $D_{\mathbb{R}_+^N}([0,\infty))$ with Skorohod topology (see [1]). It can be proved, as in [21, Prop 9.3 p 246], that the set $\mathcal{C}$ is relatively compact and that all the fluid limits $\bar{Z}$ are continuous.

In order to prove ergodicity of the process $(N(t))$, we just have to prove that there exists a time T such that for any initial condition of $(\bar{Z}(t))$, for all $t \ge T$, $\bar{Z}(t) = 0$ (see [6]). On the contrary, in order to prove transience, we have to prove that there exists a time T such that after T, any fluid limit $(\bar{Z}(t))$ increases linearly (see [17]). For that purpose, we have to characterize the fluid limits.

First, we consider fluid limits such that there exists $2 \le k_0 \le L$ with $\bar{Z}_{k_0}(0) > 0$. At the stochastic level, for each $k \ge 2$, class k can use an arbitrarily large part of link k leaving almost nothing to class 0; for any $\varepsilon > 0$, since $\theta_0^{k-1}(n \odot a) \le 1$, if n_k is large enough, we have

$$\phi_k(n) \ge 1 - \varepsilon, \text{ and } \theta_0^k(n \odot a) \le \varepsilon.$$

Thus, at fluid level, the throughput for $(\bar{Z}_k(t))$ is always 1 if $\bar{Z}_k(t) > 0$. On the contrary, the throughput for $(\bar{Z}_0(t))$ is 0 as long as there exists k_0 with $\bar{Z}_{k_0}(t) > 0$. We can prove, as in [21, Prop 9.4, p247], the following proposition.

Proposition 1. *If $(\bar{Z}(t))$ is a fluid limit of the system and there exists some time interval $[0, t_0]$ such that for any $t \in [0, t_0]$, there is some k_0 in $\{2, \dots, L\}$ such that $\bar{Z}_{k_0}(t) > 0$ then, almost surely, $(\bar{Z}(t))$ is differentiable on $[0, t_0]$ and satisfies for all $t \in [0, t_0]$,*

$$\dot{\bar{Z}}_0(t) = \lambda_0, \tag{6}$$

$$\dot{\bar{Z}}_1(t) = \lambda_1 - \mu_1 \frac{\bar{Z}_1(t)}{\bar{Z}_0(t) + \bar{Z}_1(t)}, \tag{7}$$

$$\dot{\bar{Z}}_k(t) = (\lambda_k - \mu_k)\mathbb{1}_{\{\bar{Z}_k(t)>0\}} \text{ for } 2 \le k \le L. \tag{8}$$

For $2 \le k \le L$, $\bar{Z}_k(t)$ thus decreases linearly to 0 if $\rho_k < 1$. Note also that $(\bar{Z}_k(t))$ for $2 \le k \le L$ does not depend on classes 0 and 1. This illustrates the strong asymmetry between classes 0 and 1 on one hand and classes $2, \dots, L$ on the other hand.

If there exists $2 \leq k_0 \leq L$ such that $\rho_{k_0} > 1$ then it is clear that the fluid limit will increase linearly to infinity and the process $(N(t))$ is transient. On the contrary, if $\rho_{k_0} < 1$ for all $2 \leq k \leq L$ then there exists a time T such that for $t \leq T$ and $2 \leq k \leq L$, $\bar{Z}_k(t) = 0$. In order to study ergodicity and transience of $(N(t))$ we then have to characterize the fluid limits such that $\bar{Z}_k(0) = 0$ for $2 \leq k \leq L$. This is the purpose of the next subsection.

3.3. **Quasi-stationary fluid limits.**

Before studying fluid limits, we need to define the average throughput of class 0 in the quasi-stationary case. This corresponds to the case where the number of flows in classes 0 and 1 is fixed and the number of flows in classes $2, \dots, L$ varies. In the following, we denote by $x_{2:L} = (x_2, \dots, x_L)$ the input rates of classes $2, \dots, L$. Fixing the number of flows in classes 0 and 1 is equivalent to considering a fixed rate α for class 0 after link 1. Since link 1 is of capacity 1, $\alpha \in [0, 1]$. Define $\tilde{\theta}_0^1(\alpha, x_{2:L}) = \alpha$ and, for $2 \leq k \leq L$,

$$\tilde{\theta}_0^k(\alpha, x_{2:L}) = \min\left(\tilde{\theta}_0^{k-1}(\alpha, x_{2:L}), \frac{\tilde{\theta}_0^{k-1}(\alpha, x_{2:L})}{\tilde{\theta}_0^{k-1}(\alpha, x_{2:L}) + x_k}\right), \tag{9}$$

$$\tilde{\psi}_k(\alpha, x_{2:L}) = \min\left(x_k, \frac{x_k}{\tilde{\theta}_0^{k-1}(\alpha, x_{2:L}) + x_k}\right). \tag{10}$$

The quantity $\tilde{\theta}_0^k(\alpha, x_{2:L})$ is the output rate of class 0 after link k and the throughput of class 0 is $\tilde{\psi}_0(\alpha, x_{2:L}) = \tilde{\theta}_0^L(\alpha, x_{2:L})$. Moreover, $\tilde{\psi}_k(\alpha, x_{2:L})$ is the throughput of class k. For $0 \leq k \leq L$ and for $n_{2:L} \in \mathbb{N}^{K-2}$, we define $\tilde{\phi}_k(\alpha, n_{2:L}) = \tilde{\psi}_k(\alpha, n_{2:L} \odot a)$.

Denote by $(\tilde{N}^{\alpha}_{2:L}(t))$ the Markov process describing the evolution of classes $2, \dots, L$ in the quasi-stationary case. It is defined on $\mathbb{N}^{K-2}$ and its transition rates are, for $2 \leq k \leq L$,

$$\begin{aligned} n_k &\to n_k + 1 : \lambda_k, \\ n_k &\to n_k - 1 : \mu_k \tilde{\phi}_k(\alpha, n_{2:L}). \end{aligned}$$

Proposition 2. *Consider a linear network with L links of capacity 1 in the quasi-stationary case, i.e., when the number of flows in classes 0 and 1 is fixed and the rate of class 0 after link 1 is α.*

The Markov process $(\tilde{N}^{\alpha}_{2:L}(t))$ describing the evolution of classes $2, \dots, L$ is ergodic if, for $2 \leq k \leq L$, $\rho_k < 1$. It is transient if there exists k_0 in $\{2, \dots, L\}$ such that $\rho_{k_0} > 1$.

Proof. It is enough to see that for $2 \leq k \leq L$,

$$\min(n_k a_k, C_k) \geq \tilde{\phi}_k(\alpha, n_{2:L}) \geq \frac{n_k a_k}{C_{k-1} + n_k a_k}$$

.

Since $C_k = 1$, if $\rho_k < 1$ for all k, there exists $\varepsilon > 0$ and η in $\mathbb{N}$ such that for all $n_{2:L}$ in $\mathbb{N}^{K-2} \setminus \{0, \dots, \eta\}^{K-2}$ and for $2 \leq k \leq L$ such that $n_k \geq \eta$,

$$\lambda_k - \mu_k \tilde{\phi}_k(\alpha, n_{2:L}) \leq -\varepsilon$$

and $(\tilde{N}^{\alpha}_{2:L}(t))$ is therefore ergodic.

Conversely, if there exists k_0 such that $\rho_{k_0} > 1$, then there exists $\varepsilon > 0$ and η such that for all $n_{2:L}$ with $n_{k_0} > \eta$,

$$\lambda_{k_0} - \mu_{k_0}\tilde{\phi}_{k_0}(\alpha, n_{2:L}) \geq \varepsilon$$

and $(\tilde{N}^{\alpha}_{2:L}(t))$ is therefore transient. □

When $(\tilde{N}^{\alpha}_{2:L}(t))$ is ergodic, denote its unique stationary distribution by $\tilde{\pi}^{\alpha}$. The average throughput of class 0 in the quasi-stationary case is then defined as follows:

$$\forall \alpha \in [0,1]\ \bar{\phi}_0(\alpha) = \mathbb{E}_{\tilde{\pi}^{\alpha}}(\tilde{\phi}_0(\alpha, .)) = \sum_{n_{2:L}\in\mathbb{N}^{K-2}} \tilde{\pi}^{\alpha}(n_{2:L})\tilde{\phi}_0(\alpha, n_{2:L}). \tag{11}$$

The average $\bar{\phi}_0$ depends on the traffic intensities and access rates of classes $2, \dots, L$. In order to establish ergodicity and transience conditions for the linear network in Theorems 1 and 2 below, we need the continuity of the function $\bar{\phi}_0$ with respect to α.

Subsequent developments rely on the following notion of stochastic domination.

Definition 1. *Let X and Y be two random variables in a partially ordered measurable space. We denote $X \leq_{\text{st}} Y$ and say that Y stochastically dominates X if, for any positive non-decreasing measurable function f, we have $\mathbb{E}[f(X)] \leq \mathbb{E}[f(Y)]$.*

On $\mathbb{R}^n$, we use the usual coordinate-wise partial orders. If x and y are in $\mathbb{R}^n$, $x \leq y$ if $x_k \leq y_k$ for all k. On the space $D(\mathbb{R}_+, \mathbb{R}^n)$, we say that $x \leq y$ if $x_k(t) \leq y_k(t)$ for all k and t.

For any two random variables X and Y with respective distributions π_X and π_Y and such that $X \leq_{\text{st}} Y$, we say that π_Y dominates π_X.

In particular, if $(X(t))$ and $(Y(t))$ are two Markov processes on $\mathbb{N}^n$ such that $(X(t)) \leq_{\text{st}} (Y(t))$ and $(X(t))$ is irreducible, the ergodicity of $(Y(t))$ implies the ergodicity of $(X(t))$ and the transience of $(X(t))$ implies the transience of $(Y(t))$. If $(Y(t))$ and $(X(t))$ are ergodic and $X(\infty)$ and $Y(\infty)$ are random variables with the stationary distributions of $(X(t))$ and $(Y(t))$ as distributions then $X(\infty) \leq_{\text{st}} Y(\infty)$. For more details on stochastic domination, see [15].

Lemma 1. *Consider a linear network with L links of capacity 1 in the quasi-stationary case and assume that $\rho_k < 1$ for $2 \leq k \leq L$, the function $\bar{\phi}_0$ defined by Equation* (11) *is continuous with respect to α on* $[0,1]$.

Proof. First, we prove that $\alpha \mapsto \tilde{\phi}_k(\alpha, n_{2:L})$ is 1-Lipschitz for all $n_{2:L}$ and k. By definition, $\alpha \mapsto \tilde{\theta}^1_0(\alpha, n_{2:L})$ is 1-Lipschitz. According to (9) and (10), $\alpha \mapsto \tilde{\theta}^2_0(\alpha, n_{2:L})$ and $\alpha \mapsto \tilde{\phi}_2(\alpha, n_{2:L})$ are defined as the minimum of two 1-Lipschitz functions and are then 1-Lipschitz functions. The result follows by recursion.

In particular, this is true for $\alpha \mapsto \tilde{\phi}_0(\alpha, n_{2:L})$. In order to prove the continuity of $\bar{\phi}_0$, we just have to prove that if a sequence (α_i) of $[0,1]$ converges to α_∞, then $\tilde{N}^{\alpha_i}_{2:L}(\infty)$ converges in distribution to $\tilde{N}^{\alpha_\infty}_{2:L}(\infty)$ and these random variables have $\tilde{\pi}^{\alpha_i}$ and $\tilde{\pi}^{\alpha_\infty}$ as respective distributions.

We first prove that $\{\tilde{\pi}^{\alpha}, \alpha \in [0,1]\}$ is tight. Note that for $2 \leq k \leq L$ and α in $[0,1]$,

$$\tilde{\phi}_k(\alpha, n_{2:L}) \geq \frac{n_k a_k}{1 + n_k a_k}. \tag{12}$$

Define the process $(\hat{N}_{2:L}(t))$ with the following transition rates for $2 \leq k \leq L$:

$$\begin{aligned} n_k &\mapsto n_k + 1 : \lambda_k, \\ n_k &\mapsto n_k - 1 : \mu_k \frac{n_k a_k}{1 + n_k a_k}. \end{aligned}$$

and such that $\hat{N}_{2:L}(0) = \tilde{N}^{\alpha}_{2:L}(0)$. The components of $(\hat{N}_{2:L}(t))$ are independent. For $2 \leq k \leq L$, we have $\rho_k < 1$ and there exist $\varepsilon > 0$ and η such that, for $n_k \geq \eta$, we have

$$\lambda_k - \mu_k \frac{n_k a_k}{1 + n_k a_k} < -\varepsilon,$$

which implies that $(\hat{N}_k(t))$ is ergodic; the ergodicity of $(\hat{N}_{2:L}(t))$ follows. Using Equation (12) and a standard coupling argument, see for instance [5, Lemma 1], we can prove that, for α in $[0,1]$ and $2 \leq k \leq L$, $(\hat{N}_k(t))$ stochastically dominates $(\tilde{N}^{\alpha}_k(t))$. It implies that $(\hat{N}_{2:L}(t))$ stochastically dominates $(\tilde{N}^{\alpha}_{2:L}(t))$ for any $\alpha \in [0,1]$. This implies that the stationary distribution $\hat{\pi}$ of $(\hat{N}_{2:L}(t))$ dominates any distribution $\tilde{\pi}^{\alpha}$. In particular, we have

$$\forall \alpha \in [0,1], \forall \kappa \in \mathbb{R},\ \tilde{\pi}^{\alpha}(\mathbb{N}^{K-2} \backslash [0,\kappa]^{K-2}) \leq \hat{\pi}(\mathbb{N}^{K-2} \backslash [0,\kappa]^{K-2}).$$

Thus, the set $\{\tilde{\pi}^{\alpha}, \alpha \in [0,1]\}$ is tight on $\mathbb{N}^{K-2}$ with the usual topology.

By tightness, we can suppose that the sequence $(\tilde{\pi}^{\alpha_i})_{i \in \mathbb{N}}$ is convergent. We call $\tilde{\pi}_{\infty}$ its limit. All we have to do now is to characterize this limit and prove its uniqueness.

Let f be a bounded function on $\mathbb{N}^{K-2}$. For any α in $[0,1]$, let $\tilde{\Omega}^{\alpha}$ denote the infinitesimal generator of $(\tilde{N}^{\alpha}_{2:L}(t))$. For all $n_{2:L} \in \mathbb{N}^{K-2}$,

$$\begin{aligned} \tilde{\Omega}^{\alpha}(f)(n_{2:L}) = & \sum_{k=2}^{L} \lambda_k (f(n_{2:L} + e_k) - f(n_{2:L})) \\ & - \sum_{k=2}^{L} \mu_k \tilde{\phi}_k(\alpha, n_{2:L}) (f(n_{2:L} - e_k) - f(n_{2:L})). \end{aligned}$$

Since $\alpha \mapsto \tilde{\phi}_k(\alpha, n_{2:L})$ is 1-Lipschitz for all $n_{2:L}$ and k and f is bounded, there exists η such that

$$\forall i \in \mathbb{N},\ \forall n_{2:L} \in \mathbb{N}^{K-2},\ |\tilde{\Omega}^{\alpha_\infty}(f)(n_{2:L}) - \tilde{\Omega}^{\alpha_i}(f)(n_{2:L})| \leq \eta |\alpha_\infty - \alpha_i|. \tag{13}$$

Because $(\tilde{\pi}^{\alpha_i})$ is tight, for any ε, there exists $\kappa > 0$ such that

$$\forall i \in \mathbb{N},\ \tilde{\pi}^{\alpha_i}([0,\kappa]^{K-2}) \geq 1 - \varepsilon. \tag{14}$$

Using equations (13)) and (14), we have

$$\lim_{i \to \infty} \int_{\mathbb{N}^{K-2}} \tilde{\Omega}^{\alpha_i}(f)(n_{2:L}) \tilde{\pi}^{\alpha_i}(dn_{2:L}) = \int_{\mathbb{N}^{K-2}} \tilde{\Omega}^{\alpha_\infty}(f)(n_{2:L}) \tilde{\pi}_{\infty}(dn_{2:L}) = 0.$$

We deduce that $\tilde{\pi}_{\infty}$ is an invariant distribution of $(\tilde{N}^{\alpha_\infty}_{2:L}(t))$ and by uniqueness, we have $\tilde{\pi}_{\infty} = \tilde{\pi}^{\alpha_\infty}$. Finally, we have

$$\lim_{i \to \infty} \bar{\phi}_0(\alpha_i) = \bar{\phi}_0(\alpha_\infty).$$

□

We are now able to characterize the fluid limits $(\bar{Z}(t))$ such that $Z_k(0) = 0$ for $2 \leq k \leq L$. The next proposition is proved in the appendix.

Proposition 3. *Consider a linear network of L links of capacity 1 and assume that $a_0 = 1$ and $a_1 = 1$.*

If $(\bar{Z}(t))$ is a fluid limit of the system such that $\bar{Z}_k(0) = 0$ for $2 \leq k \leq L$, then almost surely

$$\dot{\bar{Z}}_0(t) = \lambda_0 - \mu_0 \bar{\phi}_0 \left(\frac{\bar{Z}_0(t)}{\bar{Z}_1(t) + \bar{Z}_0(t)} \right), \tag{15}$$

$$\dot{\bar{Z}}_1(t) = \lambda_1 - \mu_1 \frac{\bar{Z}_1(t)}{\bar{Z}_1(t) + \bar{Z}_0(t)}, \tag{16}$$

$$\dot{\bar{Z}}_k(t) = 0 \quad \textit{for } 2 \leq k \leq L \tag{17}$$

hold for all $t \in \mathbb{R}_+$ where $\bar{\phi}_0$ is the average throughput of class 0 in the quasi-stationary case defined by Equation (11).

This proposition shows that, at the fluid time scale, there is a separation of time scales between classes 0 and 1 and $2, \dots, L$. From the point of view of classes 0 and 1, classes $2, \dots, L$ are quasi-stationary and there is an averaging because they evolve infinitely faster. From the point of view of classes $2, \dots, L$, the ratio of classes 0 and 1 is constant. This is a further illustration of the asymmetry between classes 0, 1 on the one hand and classes $2, \dots, L$ on the other hand.

3.4. **Stability of a linear network.** Now that we have characterized the fluid limits of the system, we can study the stability conditions of the linear network. Theorem 1 gives a sufficient condition for stability and Theorem 2 gives a sufficient condition for transience of $(N(t))$.

Theorem 1. *Consider a linear network of L links of capacity* 1.
If $\rho_k < 1$ for $2 \leq k \leq L$ and

$$\rho_0 < \inf_{1-\rho_1 \leq x \leq 1} \bar{\phi}_0(x)$$

then the network is stable, i.e., *$(N(t))$ is ergodic.*

Proof. In order to prove ergodicity, we just have to prove that there exists a time T such that for any initial condition of $(\bar{Z}(t))$, for all $t \geq T$, $\bar{Z}(t) = 0$ (see [6]).

We consider a general fluid limit $(\bar{Z}(t))$. As proved in Proposition 1, as long as there exists k_0 such that $\bar{Z}_{k_0}(t) > 0$, $(\bar{Z}(t))$ satisfied Equations (6), (7) and (8). Since $\rho_k < 1$ for $2 \leq k \leq L$, there exists a finite time T_0 such that, for all $k \geq 0$ and $t \geq T_0$, $\bar{Z}_k(t) = 0$. According to the strong Markov property, the study is reduced to the case where the initial state of the fluid limit verifies $\bar{Z}_0(0) + \bar{Z}_1(0) = 1$ and $\bar{Z}_k(0) = 0$ for $2 \leq k \leq L$. According to Proposition 3, $(\bar{Z}(t))$ satisfies (15), (16) and (17). In particular, for all $t \geq 0$ and $2 \leq k \leq L$, we have $\bar{Z}_k(t) = 0$, we then just have to study the behavior of $(\bar{Z}_0(t), \bar{Z}_1(t))$.

We define the following function:

$$\forall \alpha \in [0, 1],\ f(\alpha) = \inf_{\alpha \leq x \leq 1} \bar{\phi}_0(x)$$

This function is continuous, non-decreasing and satisfies $f(\alpha) \leq \bar{\phi}_0(\alpha)$ for all $\alpha \in [0,1]$. We define $(F(t))$ such that $F_0(0) = \bar{Z}_0(0)$, $F_1(0) = \bar{Z}_1(0)$ and for all $t \geq 0$,

$$\dot{F}_0(t) = \lambda_0 - \mu_0 f\left(\frac{F_0(t)}{F_0(t)+F_1(t)}\right), \tag{18}$$

$$\dot{F}_1(t) = \lambda_1 - \mu_1 \frac{F_1(t)}{F_0(t)+F_1(t)}. \tag{19}$$

Since we have $\bar{\phi}_0(\alpha) \geq f(\alpha)$, we can deduce for all $t \geq 0$, $\bar{Z}_0(t) \leq F_0(t)$ and $\bar{Z}_1(t) \leq F_1(t)$. This follows from the following.

- If $\bar{Z}_0(t) = F_0(t)$ and $\bar{Z}_1(t) = F_1(t)$ then $\dot{\bar{Z}}_0(t) \leq \dot{F}_0(t)$ and $\dot{\bar{Z}}_1(t) \leq \dot{F}_1(t)$;
- if $\bar{Z}_0(t) < F_0(t)$ and $\bar{Z}_1(t) = F_1(t)$ then $\dot{\bar{Z}}_1(t) \leq \dot{F}_1(t)$;
- if $\bar{Z}_0(t) = F_0(t)$ and $\bar{Z}_1(t) < F_1(t)$ then $\dot{\bar{Z}}_0(t) \leq \dot{F}_0(t)$.

To prove the stability of $(\bar{Z}(t))$, it is enough to prove that $(F(t))$ will return to 0 in finite time. Let $\alpha(t) = F_0(t)/(F_0(t)+F_1(t))$. We have

$$\dot{\alpha}(t) = \frac{1}{F_0(t)+F_1(t)}\left[\left(\lambda_0 - \mu_0 f(\alpha(t))\right)(1-\alpha(t)) - \left(\lambda_1 - \mu_1(1-\alpha(t))\right)\alpha(t)\right]. \tag{20}$$

Let $\beta(t) = \left(\lambda_0 - \mu_0 f(\alpha(t))\right)(1-\alpha(t)) - \left(\lambda_1 - \mu_1(1-\alpha(t))\right)\alpha(t)$. So that

$$\dot{\alpha}(t) = \frac{\beta(t)}{F_0(t)+F_1(t)}. \tag{21}$$

We also define $\alpha_0 = \max\{\alpha \in [0,1],\ f(\alpha) = \rho_0\}$. Since $\rho_0 < f(1-\rho_1)$, we have $\alpha_0 < 1-\rho_1$. Further, for t_0 such that $\alpha(t) = \alpha_0$ and t_1 such that $\alpha(t_1) = 1-\rho_1$,

$$\beta(t_0) = \alpha_0(\mu_1(1-\alpha_0) - \lambda_1) > 0,$$
$$\beta(t_1) = \rho_1(\lambda_0 - \mu_0 f(1-\rho_1)) < 0.$$

Since f is continuous and non-decreasing, there exists $\kappa > 0$ and $\eta > 0$ such that if $\alpha(t) \leq \alpha_0 + \eta$, then $\beta(t) \geq \kappa$ and if $\alpha(t) \geq 1-\rho_1-\eta$, then $\beta(t) \leq -\kappa$.

As a consequence, we deduce from Equation (21) that

$$\dot{\alpha}(t) \geq \frac{\kappa}{F_0(t)+F_1(t)} \text{ if } \alpha(t) \leq \alpha_0 + \eta,$$
$$\dot{\alpha}(t) \leq -\frac{\kappa}{F_0(t)+F_1(t)} \text{ if } \alpha(t) \geq 1-\rho_1-\eta.$$

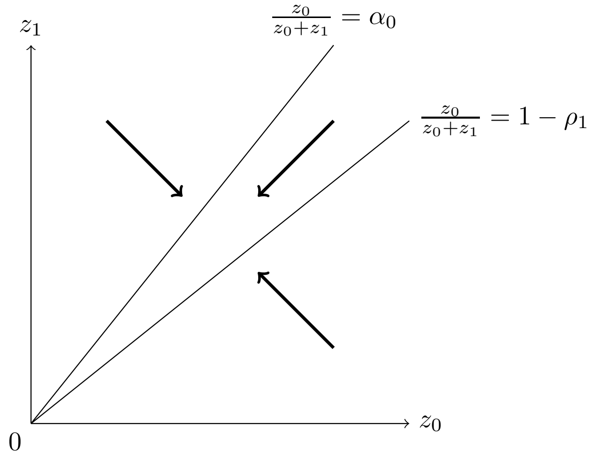
Thus, if $\alpha(0) \in [\alpha_0+\eta, 1-\rho_1-\eta]$, $\alpha(t) \in [\alpha_0+\eta, 1-\rho_1-\eta]$ for all $t > 0$.

For all $t \geq 0$, we have

$$\begin{aligned} F_0(t)+F_1(t) &\leq F_0(0)+F_1(0)+(\lambda_0+\lambda_1)t, \\ &\leq 1+(\lambda_0+\lambda_1)t, \end{aligned}$$

and we deduce that if $\alpha(0)$ is in $[0, \alpha_0+\eta]$ and as long as $\alpha(t)$ stays in $[0, \alpha_0+\eta]$, we have

$$\begin{aligned} \alpha(t) &\geq \int_0^t \frac{\kappa ds}{1+(\lambda_0+\lambda_1)s} \\ &\geq \frac{\kappa}{\lambda_0+\lambda_1}\log\left(1+(\lambda_0+\lambda_1)t\right). \end{aligned}$$



z_1
$\frac{z_0}{z_0+z_1} = \alpha_0$
$\frac{z_0}{z_0+z_1} = 1 - \rho_1$
0
z_0

FIGURE 3. Dynamics of $(F_0(t), F_1(t))$

Similarly, if $\alpha(0)$ is in $[1-\rho_1-\eta, 1]$ and $\alpha(t)$ stays in $[1-\rho_1-\eta, 1]$, we have

$$\begin{aligned}\alpha(t) &\leq 1 - \int_0^t \frac{\kappa ds}{1+(\lambda_0+\lambda_1)s} \\ &\leq 1 - \frac{\kappa}{\lambda_0+\lambda_1}\log\left(1+(\lambda_0+\lambda_1)t\right).\end{aligned}$$

We then define

$$T_1 = \frac{1}{\lambda_0+\lambda_1}\exp\left(\frac{\max(\alpha_0+\eta, \rho_1+\eta)(\lambda_0+\lambda_1)}{\kappa}\right)$$

and if $\alpha(0) \in [0, \alpha_0+\eta] \cup [1-\rho_1-\eta, 1]$ then $\alpha(T_1) \in [\alpha_0+\eta, 1-\rho_1-\eta]$. Finally, for all $t \geq T_1$, $\alpha(t) \in [\alpha_0+\eta, 1-\rho_1-\eta]$.

Now, we know that $\alpha(t)$ will reach $[\alpha_0+\eta, 1-\rho_1-\eta]$ in finite time and stay in that interval; we just have to study the behavior of F when $\alpha(0)$ is in $[\alpha_0+\eta, 1-\rho_1-\eta]$. Using equations (18) and (19), we have that, if $\alpha(0) \in [\alpha_0+\eta, 1-\rho_1-\eta]$, then, for all $t \geq 0$,

$$\begin{aligned}\dot{F}_0(t) &\leq -\mu_0\left(f(\alpha_0+\eta) - \rho_0\right) < 0, \\ \dot{F}_1(t) &\leq -\mu_1\eta\end{aligned}$$

and the two components decrease at least linearly to 0 in finite time. There exists T_2 such that for any fluid limit, for all $t \geq T_2$, $F(t) = 0$ and thus $\bar{Z}(t) = 0$. □

The dynamics of $(F_0(t), F_1(t))$ described in this proof is represented in Figure 3. Theorem 1 gives a sufficient condition for stability. The next theorem gives a sufficient condition for transience. The arguments of the proof are very similar.

Theorem 2. *Consider a linear network of L links of capacity 1. If there exists k_0 in $\{0, \ldots, L\}$ such that $\rho_{k_0} > 1$ or, if for all k in $\{0, \ldots, L\}$, $\rho_k < 1$ and*

$$\rho_0 > \sup_{0 \leq x \leq 1-\rho_1} \bar{\phi}_0(x),$$

then the network is unstable, i.e., *$(N(t))$ is transient.*

Proof. In order to prove the transience of the process, we just have to prove that there exists a time T such that after T, any fluid limit $(\bar{Z}(t))$ increases linearly (see [17]).

We consider a fluid limit $(\bar{Z}(t))$. If there is a k_0 such that $\bar{Z}_{k_0}(0) > 0$ then Equations (6), (7) and (8) are valid. It is obvious that, if there exists k_0 such that $\rho_{k_0} > 1$ then $(\bar{Z}_k(t))$ increases linearly and the process $(N(t))$ is transient.

We suppose now that $\rho_k < 1$ for all k in $\{0, \dots, L\}$. In that case, there is a time T_0 such that, for all k in $\{2, \dots, L\}$ and $t \geq T_0$, $\bar{Z}_k(t) = 0$. According to the strong Markov property, we just have to study the fluid limits such that $\bar{Z}_k(0) = 0$ for $2 \leq k \leq L$. In that case, $\bar{Z}_k(t) = 0$ for $2 \leq k \leq L$ and we just have to study the dynamics of $(\bar{Z}_0(t), \bar{Z}_1(t))$.

We define the following function

$$g(\alpha) = \sup_{0 \leq x \leq \alpha} \bar{\phi}_0(x).$$

This function is continuous, non-decreasing and, for any α in $[0,1]$ satisfies $g(\alpha) \geq \bar{\phi}_0(\alpha)$. We also define the process $(G(t))$ such that $G(0) = \bar{Z}(0)$ and

$$\dot{G}_0(t) = \lambda_0 - \mu_0 g\left(\frac{G_0(t)}{G_0(t) + G_1(t)}\right), \tag{22}$$

$$\dot{G}_1(t) = \lambda_1 - \mu_1 \frac{G_0(t)}{G_0(t) + G_1(t)}. \tag{23}$$

As previously, we can prove that, for all $t \geq 0$, $G_0(t) \leq \bar{Z}_0(t)$ and $G_1(t) \leq \bar{Z}_1(t)$. So, we just have to prove that the process $(G(t))$ increases linearly to infinity in order to prove the transience of $(N(t))$.

We define $\alpha_0 = \min\{\alpha \in [0,1],\ g(\alpha) = \rho_0\}$. Since $\rho_0 > g(1 - \rho_1)$, we have $\alpha_0 > 1 - \rho_1$. Define $\alpha(t) = G_0(t)/(G_0(t) + G_1(t))$.

As in the proof of Theorem 1, we can show that there exists $\eta > 0$ such that, for any initial state $\alpha(0)$, after some finite time T_1, $\alpha(t)$ reaches and stays in $[1 - \rho_1 + \eta, \alpha_0 - \eta]$. We then just have to study the dynamics of G when $\alpha(0)$ is in $[1 - \rho_1 + \eta, \alpha_0 - \eta]$.

Using equations (22) and (23), we have that, if $\alpha(t) \in [1 - \rho_1 + \eta, \alpha_0 - \eta]$, then

$$\begin{aligned} &\dot{G}_0(t) \geq \mu_0 \left(\rho_0 - g(\alpha_0 - \eta)\right) > 0, \\ &\dot{G}_1(t) \geq \mu_1 \eta. \end{aligned}$$

Thus, for any initial conditions, for all $t \geq T_1$, $G(t)$ increases linearly to infinity and the theorem is proved. □

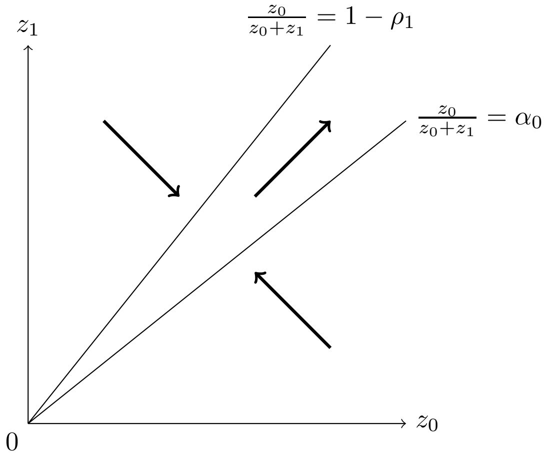
The dynamics of $(G_0(t), G_1(t))$ described in this proof is represented in Figure 4. In particular, we can remark that when the network is unstable, there is always a time after which both classes 0 and 1 of the fluid limit increase linearly to infinity.

Remark 1. *The stability region of the network is not reduced to* $\{0\}$ *since* $\inf_{1-\rho_1 \leq x \leq 1} \bar{\phi}_0(x) > 0$ *when* $\rho_1 < 1$ *and it is strictly included in the optimal stability region since* $\sup_{0 \leq x \leq 1-\rho_1} \bar{\phi}_0(x) < \min_k (1 - \rho_k)$.

Corollary 1. *Consider a linear network with two links of capacity* 1.

This network is stable if $\rho_k < 1$ *for all* $0 \leq k \leq 2$ *and* $\rho_0 < \bar{\phi}_0(1 - \rho_1)$.

This network is unstable if there exists k_0 *in* $\{0, 1, 2\}$ *such that* $\rho_{k_0} > 1$ *or if* $\rho_k < 1$ *for* $0 \leq k \leq 2$ *and* $\rho_0 > \bar{\phi}_0(1 - \rho_1)$.



z_1
$\frac{z_0}{z_0+z_1} = 1-\rho_1$
$\frac{z_0}{z_0+z_1} = \alpha_0$
z_0
0

FIGURE 4. Dynamics of $(G_0(t), G_1(t))$

Proof. All that we have to prove is that the function $\bar\phi_0$ is strictly increasing.

Consider the functions $\tilde\phi_0$, $\tilde\phi_2$, the processes $(\tilde N_2^\alpha(t))$ and their stationary distribution $\tilde\pi^\alpha$ as defined in section 3.3. We assume that $\rho_2 < 1$.

The process $(\tilde N_2^\alpha(t))$ is one-dimensional and for $\alpha_1 \le \alpha_2$, for all n_2, $\tilde\phi_k(\alpha_1, n_2) \ge \tilde\phi_k(\alpha_2, n_2)$. This implies $(\tilde N_2^{\alpha_2}(t)) \ge_{\text{st}} (\tilde N_2^{\alpha_1}(t))$ and $\tilde\pi^{\alpha_2}$ dominates $\tilde\pi^{\alpha_1}$.

For any $\alpha \in [0,1]$ and any $n_2 \in \mathbb{N}$,

$$\tilde\phi_0(\alpha, n_2) + \tilde\phi_2(\alpha, n_2) = \min(n_2 a_2 + \alpha, 1).$$

The function $n_2 \mapsto \tilde\phi_0(\alpha, n_2) + \tilde\phi_2(\alpha, n_2)$ is therefore non-decreasing.

Applying the definition of stochastic domination, we have

$$\mathbb{E}_{\tilde\pi^{\alpha_1}}(\tilde\phi_0(\alpha_1, .) + \tilde\phi_2(\alpha_1, .)) \le \mathbb{E}_{\tilde\pi^{\alpha_2}}(\tilde\phi_0(\alpha_1, .) + \tilde\phi_2(\alpha_1, .)).$$

For any $n_2 \in \mathbb{N}$, we have $\tilde\phi_0(\alpha_2, n_2) + \tilde\phi_2(\alpha_2, n_2) \ge \tilde\phi_0(\alpha_1, n_2) + \tilde\phi_2(\alpha_1, n_2)$. Since $\alpha_1 < \alpha_2 \le 1$, we have $\phi_0(\alpha_2, 0) > \phi_0(\alpha_1, 0)$ and we can conclude

$$\mathbb{E}_{\tilde\pi^{\alpha_1}}(\tilde\phi_0(\alpha_1, .) + \tilde\phi_2(\alpha_1, .)) < \mathbb{E}_{\tilde\pi^{\alpha_2}}(\tilde\phi_0(\alpha_2, .) + \tilde\phi_2(\alpha_2, .)).$$

Using the fact that $\mathbb{E}_{\tilde\pi^\alpha}(\tilde\phi_2(\alpha, .)) = \rho_2$, we can conclude that if $\alpha_1 < \alpha_2$, then $\bar\phi_0(\alpha_1) < \bar\phi_0(\alpha_2)$. ☐

4. ASYMPTOTIC STABILITY

From the results of the previous section, we know that ergodicity conditions in general depend on the access rates a_k. In this section, we qualify this dependence as the access rates become asymptotically small. In the next subsection, we introduce a scaling on the access rates in order to understand the qualitative behavior of networks when the access rates become small. In subsection 4.2, we use this scaling to determine the limit of $\bar\phi_0$ when the access rates tend to 0 and then deduce that linear networks are asymptotically optimal. In subsection 4.3, we use the same scaling to determine the asymptotic optimality of upstream trees. Subsections 4.2 and 4.3 are independent.

4.1. **Scaling over the access rates and flow sizes.** We fix all network parameters except the arrival rates, the mean size of flows and the access rates. For each $\beta \in \mathbb{N}$, define the process $(N_\beta(t))$ describing the evolution of the number of flows in each class in a network where the access rate of each class k becomes a_k/β, the arrival rate becomes $\lambda_k \beta$ and the inverse of the mean size $\beta\mu_k$.

In this proof and in the proof in the appendix, we will need the definition of an increasing process of a martingale. If $(M(t))$ is a square-integrable martingale on $\mathbb{R}$ null at 0, $(\langle M\rangle_t)$ is the (essentially unique) increasing process such that $(M^2(t) - \langle M\rangle_t)$ is a martingale. If $(M(t))$ and $(N(t))$ are two square-integrable martingales on $\mathbb{R}$ null at 0, $(\langle M, N\rangle_t)$ is the (essentially unique) increasing process such that $(M(t)N(t) - \langle M, N\rangle_t)$ is a martingale. For more information on martingales and increasing processes, see [22].

Theorem 3. *Consider an acyclic network with L links and K classes.*
If

$$\lim_{\beta\to\infty} \frac{1}{\beta} a \odot N_\beta(0) = \bar{X}(0),$$

then $(\beta^{-1} a \odot N_\beta(t))$ converges in probability uniformly on compact sets to $(\bar{X}(t))$ such that

$$\dot{\bar{X}}_k(t) = a_k\lambda_k t - a_k\mu_k\psi_k(\bar{X}(t)), \quad \text{for } 1 \le k \le K. \tag{24}$$

The convergence mentioned in this theorem is the uniform convergence in probability on compact sets for the space $D_{\mathbb{R}_+^N}([0,\infty))$ with Skorohod topology (see [1]).
Proof. We define the process $(M_\beta(t))$ such that

$$M_{\beta,k}(t) = a_k \left(\frac{N_{\beta,k}(t)}{\beta} - \frac{N_{\beta,k}(0)}{\beta} - \lambda_k t + \mu_k \int_0^t \psi_k \left(\frac{1}{\beta} a \odot N_\beta(s) \right) \mathrm{d}s \right), \tag{25}$$

for $1 \le k \le K$. The martingale characterization (see [23]) of the Markov jump process $(\beta^{-1} a \odot N_\beta(t))$ shows that $(M_\beta(t))$ is a martingale and its increasing processes are given by, for $1 \le k, l \le L$ and $k \ne l$,

$$\langle M_{\beta,k}\rangle_t = \frac{a_k}{\beta} \left(\lambda_k t + \mu_k \int_0^t \psi_k \left(\frac{1}{\beta} a \odot N_\beta(s) \right) \mathrm{d}s \right), \tag{26}$$

$$\langle M_{\beta,k}, M_{\beta,j}\rangle_t = 0. \tag{27}$$

Since ψ_k is bounded by a constant C, we have $\langle M_{\beta,k}\rangle_t \le a_k(\lambda_k + C\mu_k)t/\beta$, for $t \ge 0$.

As $(M_\beta(t))$ is a martingale, we can use Doob's inequality. For any $t > 0$ and $\varepsilon > 0$,

$$\begin{aligned}\mathbb{P}\left(\sup_{0\le s\le t}\|M_\beta\|_\infty(s)\ge\varepsilon\right) &\le \sum_{k=1}^{K}\mathbb{P}\left(\sup_{0\le s\le t}\|M_{\beta,k}\|_\infty(s)\ge\varepsilon\right)\\ &\le \frac{K}{\varepsilon^2}\max_k\mathbb{E}\left({M_{\beta,k}}^2(t)\right),\\ &\le \frac{K}{\varepsilon^2}\max_k\langle M_{\beta,k}\rangle_t,\\ &\le \frac{Kt}{\varepsilon^2\beta}\max_k a_k(\lambda_k+C\mu_k).\end{aligned}$$

Thus, $(M_\beta(t))$ converges to 0 in probability uniformly on any compact when $\beta\to+\infty$.

We now consider the random variable $\sup_{0\le s\le t}\left\|\beta^{-1}a\odot N_\beta(t)-\bar{X}(t)\right\|_\infty$ and show that it converges in distribution to 0. Define $Z_\beta(t)=\beta^{-1}a\odot N_\beta(t)-\bar{X}(t)$. Using (25),

$$\begin{aligned}Z_{\beta,k}(t) =&\frac{1}{\beta}a\odot N_{\beta,k}(0)-\bar{X}_k(0)+M_{\beta,k}(t)\\ &-\mu_k\int_0^t\left(\psi_k\left(\frac{1}{\beta}a\odot N_\beta(s)\right)-\psi_k(\bar{X}(s))\right)\mathrm{d}s,\quad\text{for } 1\le k\le K.\end{aligned}$$

The ψ_k are all κ-Lipschitz for some $\kappa>0$ and, for $1\le k\le K$,

$$\begin{aligned}\sup_{0\le s\le t}|Z_{\beta,k}(s)|\le&\left|\frac{a_k}{\beta}N_{\beta,k}(0)-\bar{X}_k(0)\right|+\sup_{0\le s\le t}|M_{\beta,k}(s)|\\ &+\kappa\mu_k\int_0^t\sup_{0\le u\le s}|Z_\beta(u)|\,\mathrm{d}s.\end{aligned}\tag{28}$$

Define the function

$$f_\beta(t)=\mathbb{E}\left(\sup_{0\le s\le t}\|Z_\beta(s)\|_\infty\right).$$

Using (28), (26) and (27), we deduce the inequality for all $s<t$,

$$f_\beta(s)\le\left\|\frac{1}{\beta}a\odot N_\beta(0)-\bar{X}(0)\right\|_\infty+\frac{\hat{a}}{\beta}\left(\hat{\lambda}+\hat{\mu}\right)s+\hat{\mu}\int_0^s f_\beta(u)\,\mathrm{d}u$$

where $\hat{a}=\max_k a_k$, $\hat{\lambda}=\max_k\lambda_k$ and $\hat{\mu}=\max_k\mu_k$.

Applying Gronwall's lemma (see [11]),

$$f_\beta(t)\le\left(\left\|\frac{1}{\beta}a\odot N_\beta(0)-\bar{X}(0)\right\|_\infty+\frac{\hat{a}}{\beta}\left(\hat{\lambda}+\hat{\mu}\right)t\right)e^{\hat{\mu}t}.$$

Thus, $f_\beta\to0$ as $\beta\to+\infty$ and $\sup_{0\le s\le t}\left\|\frac{1}{\beta}a\odot N_\beta(s)-\bar{X}(s)\right\|_\infty$ converges in distribution to 0. In particular, for $\varepsilon>0$,

$$\lim_{\beta\to+\infty}\mathbb{P}\left(\sup_{0\le s\le t}\left\|\frac{1}{\beta}a\odot N_\beta(s)-\bar{X}(s)\right\|_\infty\ge\varepsilon\right)=0.$$

Hence, $(\beta^{-1} a \odot N_\beta(t))$ converges to $(\bar{X}(t))$ in probability uniformly on compact sets. □

The processes $(\beta^{-1} a \odot N_\beta(t))$ converge in distribution, as β tends to infinity, to a process $(\bar{X}(t))$ which is completely deterministic. This process has a fixed point if and only if there exists $x \in \mathbb{R}_+^K$ such that

$$\lambda_k - \mu_k \psi_k(x) = 0 \quad \text{for } 1 \le k \le K. \tag{29}$$

Proposition 4. *Consider an acyclic network with L links and K classes.*

$(\bar{X}(t))$ admits a unique fixed point if the optimal stability conditions (4) *are satisfied:*

$$\sum_{k: l \in r_k} \rho_k < C_l \text{ for } 1 \le l \le L.$$

Conversely, if there exists a link l_0 such that

$$\sum_{k: l_0 \in r_k} \rho_k > C_{l_0}$$

then $(\bar{X}(t))$ does not admit a fixed point.

Proof.

By definition of acyclic networks, we suppose that the links are numbered in a such a way that the links on a route of any class are an increasing sequence. By definition, any fixed point $x = (x_1, \ldots, x_K)$ satisfies

$$\psi_k(x) = \rho_k, \quad \text{for } 1 \le k \le K.$$

We first suppose that the optimal stability conditions (4) are satisfied. First, note that if $x = (x_1, \ldots, x_K)$ satisfies the optimal stability conditions, then for all k, $\psi_k(x) = x_k$. The traffic intensities $(\rho_1, \ldots, \rho_K)$ are then a fixed point and this is the only fixed point which statisfies the optimal stability conditions.

On the contrary, if x is such that there exists l_0 with

$$\sum_{k: l_0 \in r_k} x_k \ge C_{l_0},$$

then, there exists l_1 which is saturated i.e.

$$\sum_{k: l_1 \in r_k} \theta_k^{l_1}(x) = C_{l_1}.$$

Since the network is acyclic, without loss of generality, we can assume that l_1 is such that, for all $l > l_1$, link l is not saturated i.e.

$$\sum_{k: l \in r_k} \theta_k^{l}(x) < C_l.$$

In that case, for all class k such that $l \in r_k$, we have $\psi_k(x) = \theta_k^{l_1}(x)$ and

$$\begin{aligned} \sum_{k: l_1 \in r_k} \psi_k(x) &= C_{l_1} \\ &> \sum_{k: l_1 \in r_k} \rho_k. \end{aligned}$$

The vector x cannot be a fixed point and the uniqueness of the fixed point is proved.

We now suppose that there exists a link l_0 such that

$$\sum_{k:l_0\in r_k} \rho_k > C_{l_0}$$

In that case, it is enough to remark that, for all $x = (x_1, \dots, x_K)$,

$$\begin{aligned}\sum_{k:l_0\in r_k} \psi_k(x) &\leq C_{l_0}\\ &< \sum_{k:l_0\in r_k} \rho_k.\end{aligned}$$

There is no fixed point. □

This proposition brings the intuition that the stability conditions for any acyclic network can be arbitrarily close to the optimal ones if the access rates are small enough. In the remainder of this section, we prove that this intuition is true in the case of linear networks and upstream trees.

4.2. **Asymptotic stability of linear networks.** We return here to the linear networks discussed in Section 3. Theorems 1 and 2 show that stability conditions depend on the function $\bar\phi_0$ and consequently on stationary distributions $(\tilde\pi^\alpha)$. In order to characterize the ergodicity conditions, we have to study the evolution of these distributions when the access rates decrease to 0.

Consider the process $(\tilde N^\alpha_{2:L}(t))$ introduced in Section 3.3 for $\alpha \in [0,1]$ under the scaling defined in Section 4.1. We call $(\tilde N^\alpha_{2:L,\beta}(t))$ the scaled process whose transition rates are given by, for $2 \leq k \leq L$,

$$\begin{aligned}&n_k \to n_k + 1 : \beta\lambda_k,\\ &n_k \to n_k - 1 : \beta\mu_k\tilde\psi_k(n\odot\beta^{-1}a)\end{aligned}$$

where the functions $\tilde\psi_k$ are defined by Equation (10). We suppose that the ergodicity conditions of this process are fulfilled, i.e., $\rho_k < 1$ for $2 \leq k \leq L$, and denote by $\tilde\pi^\alpha_\beta$ the stationary distribution of $(\beta^{-1}a_{2:L}\odot\tilde N^\alpha_{2:L,\beta}(t))$.

As in Section 4.1, when β tends to infinity, the processes $(\beta^{-1}a_{2:L}\odot\tilde N^\alpha_{2:L,\beta}(t))$ converge in distribution to a deterministic limit that we call $(\bar X^\alpha(t))$. This process has a unique fixed point that we call $\gamma(\alpha)$ which is the solution of the following equations:

$$\lambda_k - \mu_k\tilde\psi_k(\alpha, x_{2:L}) = 0 \text{ for } 2 \leq k \leq L.$$

Using the definition of $\tilde\psi_k$, $\gamma(\alpha)$ can be built recursively yielding:

$$\gamma_k(\alpha) = \max\left(\rho_k, \frac{\rho_k}{1-\rho_k}\min\left(\alpha, \min_{2\leq j\leq k-1}(1-\rho_j)\right)\right) \text{ for } 2 \leq k \leq L. \tag{30}$$

The next proposition states the convergence of the stationary distributions $\tilde\pi^\alpha_\beta$ to the Dirac measure at $\gamma(\alpha)$ for all $\alpha \in [0,1]$ and the convergence of $\bar\phi_0$.

Proposition 5. *Consider a linear network with L links in the quasi stationary regime. The set* $\{\tilde\pi^\alpha_\beta,\ \alpha\in[0,1],\ \beta\in\mathbb{N}\}$ *is tight. For any* $\alpha \in [0,1]$, *the stationary distribution* $(\tilde\pi^\alpha_\beta)$ *converges to* $\delta_{\gamma(\alpha)}$ *when* $\beta \to +\infty$.

If $\bar\phi_{0,\beta}$ *is the function such that*

$$\bar\phi_{0,\beta}(\alpha) = \int_{\mathbb{R}^{L-1}} \tilde\psi_0(\alpha, x_{2:L})\tilde\pi^\alpha_\beta(\mathrm{d}x_{2:L}), \quad \textit{for } \alpha \in [0,1], \tag{31}$$

then $\bar{\phi}_{0,\beta}$ *converges pointwise on* $[0,1]$ *to*

$$\bar{\phi}_{0,\infty} : \alpha \mapsto \min\left(\alpha, \min_{2\leq k\leq L}(1-\rho_k)\right), \quad \textit{when } \beta \to +\infty. \tag{32}$$

Moreover, for all $\alpha \in [0,1]$,

$$\lim_{\beta\to+\infty} \inf_{\alpha\leq u\leq 1} \bar{\phi}_{0,\beta}(u) = \bar{\phi}_{0,\infty}(\alpha).$$

The tightness and the convergence mentioned in this proposition is the convergence of probability distributions on $\mathbb{R}_+^{K-2}$ with the usual topology. *Proof.* First, we have to prove that the set $\{\tilde{\pi}_\beta^\alpha,\ \alpha\in[0,1],\ \beta\in\mathbb{N}\}$ is tight.

Note that for $\alpha\in[0,1]$ and for $k\geq 2$,

$$\tilde{\psi}_k(\alpha, \beta x_{2:L}) \geq \frac{n_k a_k}{\beta + n_k a_k}.$$

Define the Markov processes $(\hat{N}_{2:L,\beta}(t))$ with transition rates:

$$\begin{aligned} n_k &\to n_k + 1 : \lambda_k \beta, \\ n_k &\to n_k - 1 : \mu_k \beta \frac{n_k a_k}{\beta + n_k a_k}. \end{aligned}$$

We assume that $\hat{N}_{2:L,\beta}(0) = \tilde{N}_{2:L,\beta}^\alpha(0)$. We then have $(\beta^{-1}a_{2:L}\odot \hat{N}_{2:L,\beta}(t)) \geq_{\text{st}} (\beta^{-1}a_{2:L}\odot \tilde{N}_{2:L,\beta}^\alpha(t))$. In order to prove that the set $\{\tilde{\pi}_\beta^\alpha,\ \alpha\in[0,1],\ \beta\in\mathbb{N}\}$ is relatively compact, it is enough to prove that $\{\hat{\pi}_\beta,\ \beta\in\mathbb{N}\}$ is tight where $\hat{\pi}_\beta$ is the invariant measure of $(\beta^{-1}a_{2:L}\odot\hat{N}_{2:L,\beta}(t))$. These are birth-death processes whose components are independent. Their invariant measures thus have a product form and it is sufficient to study the one-dimensional case:

$$\hat{\pi}_\beta(n_2\beta a_2) = (1-\rho_2)^{\beta a_2^{-1}+1}\rho_2^{n_2}\frac{\Gamma\left(\frac{\beta}{a_2}+1+n_2\right)}{\Gamma\left(\frac{\beta}{a_2}+1\right)n_2!}$$

where Γ is the usual gamma function

$$\Gamma(z) = \int_0^{+\infty} t^{z-1}e^{-t}\,\mathrm{d}t, \quad \text{for } z>0.$$

$\hat{\pi}_\beta$ is a negative binomial distribution and we have

$$\hat{\pi}_\beta([A,+\infty[) = \frac{\int_{\rho_2}^1 t^{\beta a_2^{-1}}(1-t)^{\lfloor \beta A/a_2\rfloor}\,\mathrm{d}t}{\int_0^1 t^{\beta a_2^{-1}}(1-t)^{\lfloor \beta A/a_2\rfloor}\,\mathrm{d}t}.$$

Thus, if $A > \rho_2/(1-\rho_2)$,

$$\lim_{\beta\to+\infty}\hat{\pi}_\beta([A,+\infty[) = 0. \tag{33}$$

Fix $\varepsilon>0$ and $A>\rho_2/(1-\rho_2)$. According to (33), there exists $\beta_0\in\mathbb{N}$ such that for all $\beta\geq\beta_0$, $\hat{\pi}_\beta([0,A])\geq 1-\varepsilon$. Additionally, there exists a compact $\Gamma_1\subset\mathbb{R}$ such that for $\beta<\beta_0$, $\hat{\pi}_\beta(\Gamma_1)\geq 1-\varepsilon$. By choosing $\Gamma=[0,A]\cup\Gamma_1$, we have $\hat{\pi}_\beta(\Gamma)\geq 1-\varepsilon$ for all $\beta\in\mathbb{N}$ and the set $\{\hat{\pi}_\beta, \beta\in\mathbb{N}\}$ is tight on $\mathbb{R}_+$ with the usual topology. Finally, the set $\{\tilde{\pi}_\beta^\alpha,\ \alpha\in[0,1],\ \beta\in\mathbb{N}\}$ is tight and, thus, relatively compact.

We now prove the convergence of the invariant measures. The infinitesimal generator $\tilde{\Omega}^{\alpha}_{\beta}$ of $(\beta^{-1}a_{2:L} \odot \tilde{N}^{\alpha}_{2:L,\beta}(t))$ is defined by

$$\begin{aligned}\tilde{\Omega}^{\alpha}_{\beta}(f)(x_{2:L}) = &\sum_{k=2}^{L} \beta\lambda_k \left(f\left(x_{2:L} + \frac{a_k}{\beta} e_k \right) - f\left(x_{2:L}\right) \right) \\ &+ \sum_{k=2}^{L} \beta\mu_k \tilde{\psi}_k(\alpha, x_{2:L}) \left(f\left(x_{2:L} - \frac{a_k}{\beta} e_k \right) - f\left(x_{2:L}\right) \right).\end{aligned}$$

The "infinitesimal generator" $\bar{\Omega}^{\alpha}$ of $(\bar{X}^{\alpha}(t))$ is defined by

$$\bar{\Omega}^{\alpha}(f)(x_{2:L}) = \sum_{k=2}^{L} \lambda_k \frac{\partial f}{\partial x_k}(x_{2:L}) - \sum_{k=2}^{L} \mu_k \tilde{\psi}_k(\alpha, x_{2:L}) \frac{\partial f}{\partial x_k}(x_{2:L}).$$

Let f be a bounded smooth function with a bounded derivative. Since $\{\tilde{\pi}_{\beta},\ \beta \in]0,1],\ \alpha \in [0,1]\}$ is tight, for any $\varepsilon > 0$, there exists a compact set $\Gamma \subset \mathbb{R}^{K-2}$ such that for all β in $\mathbb{N}$ and α in $[0,1]$,

$$\int_{\mathbb{R}_+^{K-2} \setminus \Gamma} f(x_{2:L}) \tilde{\pi}^{\alpha}_{\beta}(\mathrm{d}x_{2:L}) \leq \varepsilon. \tag{34}$$

Since f and its derivative are bounded and the $\tilde{\psi}_k$ are γ-Lipschitz for some γ, there exists η such that for x in Γ,

$$|\tilde{\Omega}^{\alpha}_{\beta}(f)(x_{2:L}) - \bar{\Omega}^{\alpha}(f)(x_{2:L})| \leq \frac{\eta}{\beta}. \tag{35}$$

The equilibrium equations give, for all α,

$$\int_{\mathbb{R}_+^{K-2}} \tilde{\Omega}^{\alpha}_{\beta}(f)(x_{2:L}) \tilde{\pi}^{\alpha}_{\beta}(\mathrm{d}x_{2:L}) = 0. \tag{36}$$

Since $\{\tilde{\pi}^{\alpha}_{\beta},\ \beta \in \mathbb{N},\ \alpha \in [0,1]\}$ is relatively compact, we can extract a convergent subsequence $(\tilde{\pi}^{\alpha_i}_{\beta_i})$ such that $\alpha_i \to \alpha$ and $\beta_i \to +\infty$. Thanks to relations (34), (35), (36) and the continuity of f and its derivative, we can write that

$$\lim_{i \to +\infty} \int_{\mathbb{R}_+^{K-2}} \tilde{\Omega}^{\alpha_i}_{\beta_i}(f)(x_{2:L}) \tilde{\pi}^{\alpha_i}_{\beta_i}(\mathrm{d}x_{2:L}) = \int_{\mathbb{R}_+^{K-2}} \bar{\Omega}^{\alpha}(f)(x_{2:L}) \bar{\pi}^{\alpha}(\mathrm{d}x_{2:L}).$$

Finally, $(\pi^{\alpha_i}_{\beta})$ converges to $\bar{\pi}^{\alpha}$ when $\beta \to +\infty$.

The convergence pointwise of $\bar{\phi}_{0,\beta}$ follows by choosing $\alpha_i = \alpha$.

Finally, for the last part of the proposition, we consider a sequence (α_i, β_i) such that $\alpha_i \to \alpha_\infty$, $\beta_i \to +\infty$ when $i \to \infty$ and, for all i, $\bar{\phi}_{0,\beta_i}(u_i) = \inf_{\alpha \leq u \leq 1} \bar{\phi}_{0,\beta_i}(u)$. We have that

$$\lim_{i \to \infty} \bar{\phi}_{0,\beta_i}(\alpha_i) = \bar{\phi}_{0,\infty}(\alpha_\infty).$$

By construction of α_i, we also have

$$\lim_{i \to \infty} \bar{\phi}_{0,\beta_i}(\alpha_i) \leq \inf_{\alpha \leq u \leq 1} \bar{\phi}_{0,\infty}(u).$$

Since $\bar{\phi}_{0,0}$ is a non-decreasing function, its implies that

$$\lim_{i \to \infty} \bar{\phi}_{0,\beta_i}(\alpha_i) = \bar{\phi}_{0,\infty}(\alpha).$$

□

We finally deduce the following theorem which is a consequence of Theorem 1 and Proposition 5.

Theorem 4. *In a linear network with L links, for any traffic intensities $(\rho_0,\dots,\rho_L)$ satisfying the optimal stability conditions (5), if the access rates $(a_0,\dots,a_L)$ are small enough, the resulting stochastic process is ergodic.*

Proof. We consider the scaled version of the process introduced in Subsection 4.1 $(N_\beta(t))$. According to Theorem 1, a sufficient condition of stability is

$$\begin{aligned}&\rho_k < 1, \quad \text{for } 0 \le k \le L,\\ &\rho_0 < \inf_{1-\rho_1 \le \alpha \le 1} \bar{\phi}_{0,\beta}(\alpha).\end{aligned}$$

Since traffic intensities $(\rho_0,\dots,\rho_L)$ satisfy optimal stability conditions (5), there exists $\varepsilon > 0$ such that

$$\begin{aligned}&\rho_k < 1, \quad \text{for } 0 \le k \le L,\\ &\rho_0 < \min_{1 \le k \le L}(1-\rho_k) - \varepsilon.\end{aligned}$$

According to Proposition 5, there exists β_0 such that for all $\beta \ge \beta_0$, we have

$$\inf_{1-\rho_1 \le \alpha \le 1} \bar{\phi}_{0,\beta}(\alpha) \ge \min_{1 \le k \le L}(1-\rho_k) - \varepsilon/2.$$

This implies that, for all $\beta \ge \beta_0$, the process $(N_\beta(t))$ is ergodic.

Finally, to conclude, it is enough to remark that the process with transition rates

$$\begin{aligned}n_k \to n_k + 1 : &\quad \lambda_k,\\ n_k \to n_k - 1 : &\quad \mu_k \psi_k(n \odot \beta^{-1} a)\end{aligned}$$

admits the same stationary measures as $(N_\beta(t))$ and is then ergodic if and only if $(N_\beta(t))$ is ergodic. □

This result means that the Tail Dropping policy is asymptotically optimal in linear networks. Figures 5 and 6 represent the stability region for classes 0 and 1, obtained by simulation, for two particular networks and illustrate this result.

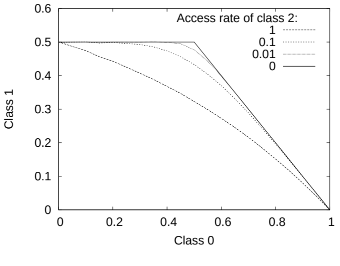


Figure 5. Stability region for classes 0 and 1 when $L = 2$ and $\rho_2 = 0.5$

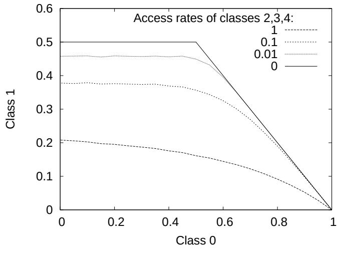

Figure 6. Stability region for classes 0 and 1 when $L = 4$ and $\rho_2, \rho_3, \rho_4 = 0.5$

4.3. **Asymptotic stability of upstream trees.** Upstream trees are a specific class of networks because they are monotonic and this will allow us to use stochastic domination to establish the asymptotic stability of upstream trees. Thanks to the monotonicity, the worst case, in the sense of stochastic domination, for a given class is when there is an infinity of flows in all other classes. When the optimal stability conditions are satisfied, we can prove that there exists a class k_0 which can get enough bandwidth to be stable even if there is an infinity of flows in all other classes. Thanks to the same scaling that we use in subsections 4.1 and 4.2, we are able to quantify the bandwidth used by the class k_0 when the access rates are decreasing to 0 and to prove that there exists a class k_1 which is stable when the access rates are small enough even if there is an infinity of flows in all classes except k_0 and k_1. We conclude by using a recursion.

In upstream trees, when two different classes go through the same link, they share the same path until they exit the network. The last link on the path of all classes is the same and it is called the root. Formally, upstream trees are defined as follows:

- **(i):** a common root link, say 1, so that $r_k(d_k) = 1$ for all classes k;
- **(ii):** for any two classes j and k, there exists m such that they only have their last m links in common; i.e, for i in $\{0, \dots, m-1\}$, $r_j(d_j - i) = r_k(d_k - i)$ and for i_k in $\{0, \dots, d_k - m\}$ and i_j in $\{0, \dots, d_j - m\}$, $r_j(i_j) \neq r_k(i_k)$.

Two examples of upstream trees are given in Figure 7. In [4], two very specific examples were shown not to be ergodic under optimal stability conditions except when the access rates tend to 0. We generalize this result.

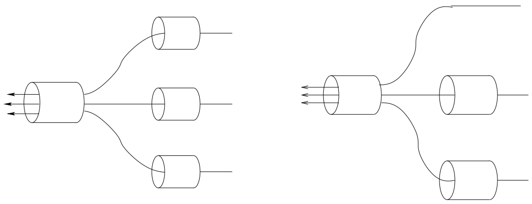

Figure 7. Examples of upstream trees

For any link l, let S_l denote the set of children of l, the links just *before* l on the path of some class:

$$S_l = \big\{ j \in \{1, \dots, L\},\ \exists k \in \{1, \dots, K\},\ \exists i,\ r_k(i) = j, r_k(i+1) = l \big\}.$$

In particular, S_1 is the set of links which are the links just before the root link on the path of all classes with a route of length longer than 1.

We suppose that there are no two classes with exactly the same path. We also suppose without loss of generality that all the links of the network can be saturated. For any link l, this implies that there is a class k_l directly entering in the network through that link, i.e., $r_{k_l}(1) = l$ or $\sum_{j \in S_l} C_j > C_l$. If a link l_0 cannot be saturated then the bandwidth allocation is the same with or without l_0 and we can remove it.

Upstream trees are monotonic in the sense that if $n \in \mathbb{N}^K$ and $m \in \mathbb{N}^K$ and $m_k = n_k$ for a given k and $m_j \geq n_j$ for $j \neq k$ then $\phi_k(m) \leq \phi_k(n)$. Thanks to this monotonicity property, the processes we study fit into the framework of [5]. We suppose that the traffic intensities satisfy the optimal stability conditions (4).

Because of the monotonicity of this network, we know that the worst case for class k_0 is when the numbers of flows in all other classes increase to infinity. We define the following allocation:

$$\forall x_{k_0} \in \mathbb{R}_+,\ \breve{\psi}^1_{k_0}(x_{k_0}) = \lim_{\eta \to \infty} \inf_{\substack{y: y_{k_0} = x_{k_0},\\ k \neq k_0, y_k > \eta}} \psi_{k_0}(y) \tag{37}$$

and $\breve{\phi}^1_{k_0}$ is such that $\breve{\phi}^1_{k_0}(n_{k_0}) = \breve{\psi}^1_{k_0}(a_{k_0} n_{k_0})$ for all $n_{k_0} \in \mathbb{N}$. We then define the Markov process $(\breve{N}^1_{k_0}(t))$ such that $\breve{N}^1_{k_0}(0) = N_{k_0}(0)$ with the transition rates

$$\begin{aligned} n_{k_0} &\to n_{k_0} + 1 : \lambda_{k_0}, \\ n_{k_0} &\to n_{k_0} - 1 : \mu_{k_0} \breve{\phi}^1_{k_0}(n_{k_0}). \end{aligned}$$

Because of the monotonicity of the considered allocations, we have that the process $(\breve{N}^1_{k_0}(t))$ stochastically dominates $(N_{k_0}(t))$ (see [5]).

In the sense of the stochastic domination, this process represents the worst case for class k_0. The next lemma shows that there is a class which is stable even in the worst case.

Lemma 2. *Consider an upstream tree and suppose the traffic intensities of this network respect the optimal stability conditions* (4). *There exists a class* k_0 *such that the Markov process* $(\breve{N}^1_{k_0}(t))$ *is ergodic.*

Proof. Because of the monotonicity of the network all that we have to prove is that there exists a class k_0 such that

$$\lim_{\eta \to +\infty} \inf_{n_1 \geq \eta, \ldots, n_K \geq \eta} \phi_{k_0}(n) > \rho_{k_0}. \tag{38}$$

If k_0 satisfies (38) then there exists $\varepsilon > 0$ and η_0 such that, for all $n_{k_0} \geq \eta_0$,

$$\lambda_{k_0} - \mu_{k_0} \breve{\phi}^1_{k_0}(n_{k_0}) \leq -\varepsilon.$$

This implies the ergodicity of $(\breve{N}^1_{k_0}(t))$. We proceed by recursion on the depth of the tree.

If the depth is 1 then there is a single class and a single link and condition (38) is obviously true.

We suppose now that the depth of the tree is $d \geq 2$. If there is a class k_0 such that $r_{k_0}(1) = 1$ then the root link is the entry point of k_0 which is the only one entering the network through 1. The worst case for class k_0 is when all links in S_1 are saturated; we have for all $n \in \mathbb{N}^K$,

$$\phi_{k_0}(n) \geq \min\left(a_{k_0} n_{k_0}, C_1 \frac{a_{k_0} n_{k_0}}{\sum_{l \in S_1} C_l + a_{k_0} n_{k_0}} \right).$$

Because the optimal conditions are satisfied, we have $\rho_{k_0} < C_1$ and there exist $\delta > 0$ and η_0 such that for all $n \in \mathbb{N}^K$ with $n_{k_0} \geq \eta_0$, we have

$$\phi_{k_0}(n) \geq \rho_{k_0} + \delta$$

which is enough to conclude.

We now suppose that there is no class directly connected to the root, i.e. there is no class k with a path of length 1. This implies that S_1 is not empty. Since the root link can be saturated, we have $\sum_{l \in S_1} C_l > C_1$. Due to optimal stability conditions, we have

$$\sum_{k=1}^{K} \rho_k < C_1$$

and we can deduce that there is a link l_0 in S_1 such that

$$\sum_{k: r_k(d_k - 1) = l_0} \rho_k < \frac{C_{l_0}}{\sum_{j \in S_1} C_j} C_1.$$

Since the link l_0 can be saturated, there is a constant η_0 such that, if for any class k going through l_0 (i.e. satisfying $r_k(d_k - 1) = l_0$), we have $n_k > \eta_0$, we have

$$\sum_{k: r_k(d_k - 1) = l_0} \theta_k^{d_k - 1}(n \odot a) = C_{l_0}.$$

Using the monotonicity of upstream trees, we can deduce that the worst case for classes going through l_0 is when all the other links in S_1 are saturated. We deduce immediately that when $n_k > \eta_0$ for all k going through l_0, we have

$$\phi_k(n) \geq \frac{C_1}{\sum_{j \in S_1} C_j} \theta_k^{d_k - 1}(n \odot a).$$

It remains to consider the case where all the links in S_1 are saturated corresponding to the case of equality in the previous equation. With these conditions, the subtree whose root link is l_0 is equivalent to an upstream tree where the capacity of link l_0 is replaced by $C_1 C_{l_0} / (\sum_{j \in S_1} C_j)$.

If there is a class k_0 such that $d_{k_0} = l_0$ then, as previously, we have

$$\lim_{\eta \to \infty} \inf_{n: n_k \geq \eta} \phi_{k_0}(n) \geq \frac{C_1 C_{l_0}}{\sum_{j \in S_1} C_j} > \rho_{k_0}$$

and k_0 satisfies (38).

If there is no class k_0 such that $d_{k_0} = l_0$ then S_{l_0} is not empty and, as previously, we can find l_1 such that

$$\sum_{k: r_k(d_k - 2) = l_1} \rho_k < C_{l_1} \frac{C_{l_0}}{\sum_{j \in S_{l_0}} C_j} \frac{C_1}{\sum_{j \in S_1} C_j}.$$

Using a recursion, we finally find k_0 satisfying (38). In addition, the links on the path of k_0 satisfy

$$\forall i \in \{1, \ldots, d_{k_0} - 1\}, \quad \sum_{k: r_{k_0}(i) \in r_k} \rho_k < C_{r_{k_0}(i)} \prod_{j=i+1}^{d_{k_0}} \frac{C_{r_{k_0}(j)}}{\sum_{l \in S_{r_{k_0}(j)}} C_l}. \tag{39}$$

□

We now perform the scaling of Section 4.1 on the process $(\breve{N}_{k_0}^1(t))$ and call the scaled process $(\breve{N}_{k_0,\beta}^1(t))$. We deduce from the above lemma that the scaled process is ergodic for all $\beta \in \mathbb{N}$. For each β, we call $\breve{\pi}_{k_0,\beta}^1$ the stationary distribution of $(\beta^{-1} a_{k_0} \breve{N}_{k_0,\beta}^1(t))$. As in Section 4.1, the process $(\beta^{-1} a_{k_0} \breve{N}_{k_0,\beta}^1(t))$ converges in probability uniformly on compact sets to a deterministic process $(\breve{X}_{k_0}^1(t))$. The next lemma shows that there is also convergence for the stationary distribution. The proof of this lemma is similar to that of Proposition 5 and is omitted. The tightness and convergence in distribution mentioned in this lemma are on the space $\mathbb{R}_+$ with its usual topology.

Lemma 3. *Consider an upstream tree and suppose that the optimal stability conditions* (4) *are satisfied by the traffic intensities. Consider* k_0 *such that* $(\breve{N}^1_{k_0}(t))$ *is ergodic. The set* $\{\breve{\pi}^1_{k_0,\beta}, \beta \in \mathbb{N}\}$ *is tight and* $\breve{\pi}^1_{k_0,\beta}$ *converges to* $\delta_{\alpha^1_{k_0}}$ *where* $\alpha^1_{k_0}$ *is the unique solution of the following equation*

$$\lambda_{k_0} - \mu_{k_0}\breve{\psi}^1_{k_0}(\alpha^1_{k_0}) = 0. \tag{40}$$

The function $\breve{\psi}^1_{k_0}$ *is defined by Equation* (37).

Now, we proceed by recursion. First, we exhibit a class k_1 which is also stable when the access rates of classes k_0 and k_1 are small enough whatever the state of other classes. For any classes k_0 and k_1, define the following allocation

$$\forall (x_{k_0}, x_{k_1}) \in \mathbb{R}^2_+,\ \breve{\psi}^2_{k_0}(x_{k_0}, x_{k_1}) = \lim_{\eta \to \infty} \inf_{\substack{y: y_{k_0} = x_{k_0} \\ y_{k_1} = x_{k_1} \\ k \neq k_i, y_k \geq \eta}} \psi_{k_0}(x) \tag{41}$$

and $\breve{\psi}^2_{k_1}$ is defined similarly. Now define $\breve{\phi}^2_{k_0}$ and $\breve{\phi}^2_{k_1}$ such that $\breve{\phi}^2_{k_i}(n_{k_0}, n_{k_1}) = \breve{\psi}^2_{k_i}(a_{k_0}n_{k_0}, n_{k_1}n_{k_1})$ for all (n_{k_0}, n_{k_1}) in $\mathbb{N}^2$. Let $(\breve{N}^2_{k_0}(t), \breve{N}^2_{k_1}(t))$ be the Markov process with the transition rates for $i = 0, 1$:

$$\begin{aligned} &n_{k_i} \to n_{k_i} + 1 : \lambda_{k_i}, \\ &n_{k_i} \to n_{k_i} - 1 : \mu_{k_i}\breve{\phi}^2_{k_i}(n_{k_0}, n_{k_1}), \end{aligned}$$

and such that $(\breve{N}^2_{k_0}(0), \breve{N}^2_{k_1}(0)) = (N_{k_0}(0), N_{k_1}(0))$. Using the monotonicity of the considered allocations, we know that process $(\breve{N}^2_{k_0}(t), \breve{N}^2_{k_1}(t))$ stochastically dominates $(N_{k_0}(t), N_{k_1}(t))$. Again, let $(\breve{N}^2_{k_0,\beta}(t), \breve{N}^2_{k_1,\beta}(t))$ denote the scaled version of $(\breve{N}^2_{k_0}(t), \breve{N}^2_{k_1}(t))$.

Lemma 4. *Consider an upstream tree and assume that the optimal stability conditions* (4) *are satisfied by the traffic intensities of this tree. Consider* k_0 *as defined in Lemmas 2 and 3.*

There exist k_1 *and* $\beta_1 \in \mathbb{N}$ *such that, for all* $\beta \geq \beta_1$*, the Markov process* $(\breve{N}^2_{k_0,\beta}(t), \breve{N}^2_{k_1,\beta}(t))$ *is ergodic. When* $\beta \geq \beta_1$*, the Markov process*

$$(\beta^{-1}a_{k_0}\breve{N}^2_{k_0,\beta}(t), \beta^{-1}a_{k_1}\breve{N}^2_{k_1,\beta}(t))$$

has a unique stationary distribution that we denote by $\breve{\pi}^2_{k_0,k_1,\beta}$*. The set*

$$\{\breve{\pi}^2_{k_0,k_1,\beta},\ \beta \in \mathbb{N}\}$$

is tight and the stationary distribution $\breve{\pi}^2_{K_0,k_1,\beta}$ *converges to* $\delta_{(\alpha^2_{k_0}, \alpha^2_{k_1})}$ *where* $(\alpha^2_{k_0}, \alpha^2_{k_1})$ *is the unique solution of the equations*

$$\begin{cases} \lambda_{k_0} - \mu_{k_0}\breve{\psi}^2_{k_0}\left(\alpha^2_{k_0}, \alpha^2_{k_1}\right) = 0, \\ \lambda_{k_1} - \mu_{k_1}\breve{\psi}^2_{k_1}\left(\alpha^2_{k_0}, \alpha^2_{k_1}\right) = 0. \end{cases} \tag{42}$$

The functions $\breve{\psi}^2_{k_0}$ *and* $\breve{\psi}^2_{k_1}$ *are defined by Equation* (41).

The tightness and convergence in distribution mentioned in this lemma are on the space $\mathbb{R}^2_+$ with its usual topology.

Proof. First, we prove that there exists k_1 such that

$$\lim_{x_{k_1}\to\infty} \breve{\psi}^2_{k_1}(\alpha^1_{k_0}, x_{k_1}) > \rho_{k_1} \tag{43}$$

where $\alpha^1_{k_0}$ is the unique solution of (40).

For all i in $\{1,\dots,d_{k_0}\}$, We define

$$\breve{\tau}^i_{k_0}(x_{k_0}) = \lim_{\eta\to\infty} \inf_{\substack{y:y_{k_0}=x_{k_0}\\ k\neq k_0, y_k\geq\eta}} \theta^i_{k_0}(y).$$

Using Lemma 3, we can prove

$$\sigma_i = \breve{\tau}^i_{k_0}\left(\alpha^1_{k_0}\right) = \lim_{\beta\to+\infty} \mathbb{E}_{\breve{\pi}^1_{k_0,\beta}}\left(\breve{\tau}^i_{k_0}\left(\beta^{-1}a_{k_0}\breve{N}^1_{k_0,\beta}\right)\right)$$

The quantity σ_i is the bandwidth used asymptotically by class k_0 in link $r_{k_0}(i)$ when all the other classes are saturated and when the access rate a_{k_0} decreases to 0. We want to prove that when a_{k_0} is small enough, class k_0 leaves enough bandwidth for other classes. First, we have the following result which states that the optimal stability conditions are met by all classes except k_0 when we remove the bandwidth asymptotically used by class k_0 in the saturated case:

$$\forall i \in \{1,\dots,d_{k_0}\}, \quad \sum_{k:r_{k_0}(i)\in r_k} \rho_k < C_{r_{k_0}(i)} - \sigma_i.$$

Indeed, for link 1, note that $\sigma_{d_{k_0}} = \rho_{k_0}$ because $\alpha^1_{k_0}$ is the solution of Equation (40) and the previous inequality is obviously true for link 1. If the route of k_0 is of length 1 the lemma is proved.

Suppose that the route of k_0 is at least of length 2. By construction of k_0, there is no class entering the network through $r_{k_0}(i)$ for i in $\{2,\dots,d_{k_0}\}$. Since any link can be saturated, this implies

$$\forall i \in \{2,\dots,d_{k_0}\},\ C_{r_{k_0}(i)} < \sum_{l\in S_{r_{k_0}(i)}} C_l.$$

Moreover, we can prove that

$$\forall i \in \{1,\dots,d_{k_0}-1\},\ \sigma_i = \prod_{j=i+1}^{d_{k_0}} \frac{\sum_{l\in S_{r_{k_0}(j)}} C_l}{C_{r_{k_0}}(j)}\rho_{k_0}.$$

Using these last two equations and Equation (39), we deduce

$$\forall i \in \{1,\dots,d_{k_0}-1\}, \quad \sum_{k:r_{k_0}(i)\in r_k} \rho_k < C_{r_{k_0}(i)} - \sigma_i.$$

Considering, for all $k\neq k_0$, the allocation

$$(x_0,\dots,x_{k_0-1},x_{k_0+1},\dots,x_K) \mapsto \psi_k\left(x_0,\dots,\alpha^1_{k_0},\dots,x_K\right)$$

and using the same procedure used to find k_0, we can find k_1 such that

$$\lim_{\eta\to\infty} \inf_{\substack{k\neq k_0 x_k\geq\eta\\ x_{k_0}=\alpha^1_{k_0}}} \psi_{k_1}(x) > \rho_{k_1}$$

which is equivalent to Equation (43).

We are now able to prove that there exists $\beta_1\in\mathbb{N}$ such that for all $\beta\geq\beta_1$, the Markov process $(\breve{N}^2_{k_0,\beta}(t), \breve{N}^2_{k_1,\beta}(t))$ is ergodic. By construction of $(\breve{N}^1_{k_0,\beta}(t))$ and

$(\breve{N}^2_{k_0,\beta}(t), \breve{N}^2_{k_1,\beta}(t))$, according to Theorem 2 of [5], we just have to prove that there exists $\beta_1 \in \mathbb{N}$ such that, for all $\beta \geq \beta_1$,

$$\rho_{k_1} < \mathbb{E}_{\breve{\pi}^1_{k_0,\beta}}\left(\liminf_{x_{k_1}\to\infty} \breve{\psi}^2_{k_1}\left(\beta^{-1}a_{k_0}\breve{N}^1_{k_0,\beta}(0), x_{k_1}\right)\right). \tag{44}$$

We deduce from (43) that there exists $b > \alpha^1_{k_0}$, $\varsigma > 0$ and η_0 such that

$$\forall x_{k_0} \leq b,\ \forall x_{k_1} \geq \eta_0,\ \breve{\psi}^2_{k_1}\left(x_{k_0}, x_{k_1}\right) \geq \rho_{k_1} + \varsigma. \tag{45}$$

We know that $\breve{\pi}^1_{k_0,\beta}$ converges to $\delta_{\alpha^1_{k_0}}$ when $\beta \to +\infty$. Thus, there exists $\beta_1 \in \mathbb{N}$, such that, for all $\beta \geq \beta_1$,

$$\breve{\pi}^1_{k_0,\beta}\left([b,\infty[\right) \leq \frac{\varsigma}{2(\rho_{k_1}+\varsigma)}. \tag{46}$$

Finally, we have that, for all $\beta \geq \beta_1$, Equation (44) is satisfied and the process $(\breve{N}^2_{k_0,\beta}(t), \breve{N}^2_{k_1,\beta}(t))$ is ergodic.

We now prove tightness. By construction, we have $(\breve{N}^1_{k_0,\beta}(t)) \geq_{\mathrm{st}} (\breve{N}^2_{k_0,\beta}(t))$ and we deduce immediately that

$$\forall c \in \mathbb{R},\ \breve{\pi}^2_{k_0,k_1,\beta}([c,\infty[\times\mathbb{R}) \leq \breve{\pi}^1_{k_0,\beta}([c,\infty[). \tag{47}$$

Moreover, according to Equations (45) and (46), for all $\beta \geq \beta_1$, there exists a process $(Y_\beta(t))$ such that $(Y_\beta(t)) \geq_{\mathrm{st}} (\breve{N}^2_{k_1,\beta}(t))$ with the following transition rates

$$\begin{aligned}
&n_{k_1} \to n_{k_1}+1 : \beta\lambda_{k_1},\\
&n_{k_1} \to n_{k_1}+1 : \beta\left(\lambda_{k_1} + \frac{\varsigma}{3}\mu_{k_1}\right)\mathbb{1}_{\{Y_\beta(t)\geq\eta_0\beta\}}.
\end{aligned}$$

$(Y_\beta(t))$ has the transition rates of a $M/M/1$ queue with $\lfloor \eta_0\beta \rfloor$ permanent clients. Let $\pi_{Y,\beta}$ denote the stationary distribution of $(\beta^{-1}Y_\beta(t))$ and we obtain immediately that

$$\begin{aligned}
\forall\beta\geq\beta_1,\ \forall\eta\geq\eta_0,\ \pi_{Y,\beta}([\eta,\infty[) &\leq \left(\frac{\lambda_{k_1}}{\lambda_{k_1}+\frac{\varsigma}{3}\mu_{k_1}}\right)^{\lfloor(\eta-\eta_0)\beta\rfloor}\\
&\leq \left(\frac{\lambda_{k_1}}{\lambda_{k_1}+\frac{\varsigma}{3}\mu_{k_1}}\right)^{\lfloor(\eta-\eta_0)\beta_1\rfloor}
\end{aligned}$$

We deduce from the previous equation that

$$\forall\beta\geq\beta_1,\ \forall\eta\geq\eta_0,\ \breve{\pi}^2_{k_0,k_1,\beta}(\mathbb{R}\times[c,\infty]) \leq \left(\frac{\lambda_{k_1}}{\lambda_{k_1}+\frac{\varsigma}{3}\mu_{k_1}}\right)^{\lfloor(\eta-\eta_0)\beta_1\rfloor} \tag{48}$$

The tightness of $\{\breve{\pi}^2_{k_0,k_1,\beta},\ \beta\geq\beta_1\}$ follows from Equations (47) and (48) and the tightness of $\{\breve{\pi}^1_{k_0,\beta},\ \beta\in\mathbb{N}\}$.

We can remark that existence and uniqueness of the solution of Equation (42) come from the monotonicity of $(\breve{\psi}^2_{k_0}, \breve{\psi}^2_{k_1})$ and from Equations (38) and (43).

The proof of convergence is similar to that used in the proof of Proposition 5. □

Using a recursion we can easily generalize the previous lemma. The principle is still the same: little by little, we decrease the access rates and the classes become stable one by one. In particular, there exists $\beta_{K-1} \in \mathbb{N}$ such that for all $\beta \geq \beta_{K-1}$, the process $(N_\beta(t))$ is ergodic where $(N_\beta(t))$ is the scaled version of $(N(t))$. We can therefore state the following.

Theorem 5. *In an upstream tree, for any traffic intensities satisfying the optimal stability conditions* (4)*, there exist positive access rates small enough such that the resulting stochastic process is ergodic.*

APPENDIX

APPENDIX A. PROOF OF PROPOSITION 3

We first give a sketch of the proof. The technical details are proved in the lemmas which follow.

We consider the process $(\bar{N}(m,t)) = ((\bar{N}_0(m,t), \bar{N}_1(m,t), \dots, \bar{N}_k(m,t)))$ such that, for all $0 \le k \le L$,

$$\bar{N}_k(m,0) = \frac{m_k}{\|m\|} \quad \text{and} \quad \bar{N}_k(m,t) = \frac{1}{\|m\|} N_k(\|m\|t), \quad \text{for } t \ge 0.$$

We consider a sequence $(m^i,\ i \in \mathbb{N})$ such that

$$\begin{aligned} &\lim_{i\to+\infty} \|m^i\| = +\infty, && \lim_{i\to+\infty} \frac{m_0^i}{\|m^i\|} = \alpha, \\ &\lim_{i\to+\infty} \frac{m_1^i}{\|m^i\|} = 1-\alpha, && \lim_{i\to+\infty} \frac{m_k^i}{\|m^i\|} = 0, \quad \text{for } 2 \le k \le L. \end{aligned} \tag{49}$$

We want to prove that the sequence of processes $(\bar{N}(m^i,t))$ converge and to characterize the limit. For that purpose, we write them as the sum of a martingale term and a continuous term and we define the process $(\bar{M}(m,t))$ such that for $t \ge 0$ and $0 \le k \le L$, we have

$$\begin{aligned} \bar{M}_k(m,t) =& \bar{N}_k(m,t) - \frac{m_k}{\|m\|} - \lambda_k t \\ &+ \mu_k \int_0^t \phi_k\left(\bar{N}_0(m,s), \bar{N}_1(m,s), N_2(\|m\|s), \dots, N_L(\|m\|s)\right) \mathrm{d}s. \end{aligned} \tag{50}$$

Because the access rates a_0 and a_1 are equal to 1, we have

$$\forall n \in \mathbb{N}^K,\ \gamma \in \mathbb{R}, \phi_k\left(\gamma n_0, \gamma n_1, n_2, \dots, n_L\right) = \phi_k\left(n_0, n_1, n_2, \dots, n_L\right)$$

If a_0 and a_1 are not equal to 1, the previous expression is true outside a compact set and it is possible to prove all the results in this section without this assumption because, at a fluid level, the first link is always saturated.

In Lemma 5, we prove that the set

$$\mathcal{C} = \left\{(\bar{N}(m^i,t)),\ i \in \mathbb{N}\right\}$$

is relatively compact and its limiting points are continuous. We can now extract a converging subsequence and we suppose that (m^i) is such that $(\bar{N}(m^i,t))$ converges in distribution to a limit that we denote $(\bar{Z}(t)) = (\bar{Z}_0(t), \bar{Z}_1(t), \dots, \bar{Z}_L(t))$ and which is continuous. In lemma 6, we characterize $(\bar{Z}_2(t), \dots, \bar{Z}_L(t))$ by proving that, for $2 \le k \le L$ and $t \ge 0$, $\bar{Z}_k(t) = 0$.

Proposition 6 is the key result in order to understand the time scale separation between classes 0 and 1 and classes $2, \dots, L$. We deduce from this lemma that

$$\left(\int_0^t \phi_k\left(\bar{N}_0(m^i,s), \bar{N}_1(m^i,s), N_2(\|m^i\|s), \dots, N_L(\|m^i\|s)\right) \mathrm{d}s,\ k = 0, 1\right)$$

converges in distribution to

$$\left(\int_0^t \bar{\phi}_0\left(\frac{\bar{Z}_0(s)}{\bar{Z}_0(s)+\bar{Z}_1(s)}\right)\mathrm{d}s,\ \int_0^t \frac{\bar{Z}_1(s)}{\bar{Z}_0(s)+\bar{Z}_1(s)}\,\mathrm{d}s\right)$$

where $\bar{\phi}_0$ characterizes the average throughput of class 0 in the quasi-stationary case as defined by Equation (11).

We can deduce from that and the fact that $(\bar{M}(m^i,t))$ converges to 0 in distribution that $(\bar{N}_0(m^i,t),\bar{N}_1(m^i,t))$ converges in distribution to

$$\left(\bar{Z}_0(0)+\lambda_0 t-\mu_0\int_0^t \bar{\phi}_0\left(\frac{\bar{Z}_0(s)}{\bar{Z}_0(s)+\bar{Z}_1(s)}\right)\mathrm{d}s,\ \bar{Z}_1(0)+\lambda_1 t-\mu_1\int_0^t \frac{\bar{Z}_1(s)}{\bar{Z}_0(s)+\bar{Z}_1(s)}\,\mathrm{d}s\right)$$

and we conclude that, almost surely,

$$\begin{aligned}
\bar{Z}_0(t) &= \bar{Z}_0(0)+\lambda_0 t-\mu_0\int_0^t \bar{\phi}_0\left(\frac{\bar{Z}_0(s)}{\bar{Z}_1(s)+\bar{Z}_0(s)}\right)\mathrm{d}s,\\
\bar{Z}_1(t) &= \bar{Z}_1(0)+\lambda_1 t-\mu_0\int_0^t \frac{\bar{Z}_1(s)}{\bar{Z}_1(s)+\bar{Z}_0(s)}\,\mathrm{d}s,\\
\bar{Z}_k(t) &= 0, \quad \text{for } 2\le k\le L
\end{aligned}$$

holds for all t in $\mathbb{R}_+$.

Lemma 5.

$$\mathcal{C}=\left\{(\bar{N}(m^i,t)),\ i\in\mathbb{N}\right\}$$

is relatively compact and its limiting points are continuous processes.

Proof. The method used here is also standard. We define w_h the modulus of continuity for any function h defined on $[0,T]$:

$$w_h(\delta)=\sup_{s,t\le T;\ |t-s|<\delta}|h(s)-h(t)|.$$

As in the proof of Theorem 3, we can prove that $(\bar{M}(m,t))$ is a martingale and its increasing processes are given by, for $0\le k,l\le K$ with $k\ne l$,

$$\begin{aligned}
\langle \bar{M}_k(m,t)\rangle &= \frac{\lambda_k t}{\|m\|}+\frac{\mu_k t}{\|m\|}\int_0^t \phi_k(\bar{N}_0(m,s),\bar{N}_1(m,s),N_2(\|m\|s),\dots,N_L(\|m\|s))\,\mathrm{d}s,\\
\langle \bar{M}_k(m,t),\bar{M}_l(m,t)\rangle &= 0.
\end{aligned}$$

Since the functions ϕ_k are bounded by 1, we deduce that

$$\langle \bar{M}_k(m,t)\rangle \le \frac{(\lambda_k+\mu_k)t}{\|m\|}.$$

By using Doob's inequality, we have that, for $\varepsilon>0$,

$$\begin{aligned}
\mathbb{P}\left(\sup_{0\le s\le t}\|\bar{M}(m,s)\|\ge\varepsilon\right) &\le \sum_{k=0}^{L}\mathbb{P}\left(\sup_{0\le s\le t}|\bar{M}_k(m,s)|\ge\frac{\varepsilon}{L}\right),\\
&\le \frac{L^2 t\sum_{k=0}^{L}\lambda_k+\mu_k}{\varepsilon^2\|m\|}
\end{aligned}$$

We deduce that if (m^i) is a sequence satisfying Equation (49) then $(\bar{M}(m^i,t))$ converges in probability to 0 uniformly on compact sets when i tends to infinity;

for any $T \leq 0$ and any $\varepsilon > 0$,

$$\lim_{i \to \infty} \mathbb{P}\left(\sup_{0 \leq t \leq T} \|\bar{M}(m^i, t)\| \geq \varepsilon \right) = 0.$$

Using Equation (50) and the previous equation, we can prove that for any $\varepsilon > 0$ and $\eta > 0$, there exist $\delta > 0$ and A such that for all $i \geq A$,

$$\mathbb{P}\left(w_{\bar{N}_k(m^i,.)}(\delta) > \eta \right) \leq \varepsilon.$$

The conditions of [1, 7.2 p81] are then fulfilled and the set $\mathcal{C}$ is relatively compact and its limiting points are continuous processes. □

We are now able to characterize $(\bar{Z}_2, \ldots, \bar{Z}_L(t))$.

Lemma 6. *We consider a sequence* (m^i) *satisfying Equation* (49) *and such that* $(N(m^i, t))$ *converges in distribution to* $(\bar{Z}(t))$*. Then the process* $(\bar{Z}(t))$ *verifies* $\bar{Z}_k(t) = 0$ *for* $2 \leq k \leq L$ *and* $t \geq 0$*.*

Proof. Define the process $(\hat{N}_{2:L}(t))$ with the following transition rates for $2 \leq k \leq L$:

$$\begin{aligned} n_k &\mapsto n_k + 1 : \lambda_k, \\ n_k &\mapsto n_k - 1 : \mu_k \frac{n_k a_k}{1 + n_k a_k}. \end{aligned}$$

and such that $\hat{N}_{2:L}(0) \geq \tilde{N}^{\alpha}_{2:L}(0)$. Clearly, $(\hat{N}_{2:L}(t))$ is ergodic and stochastically dominates $(N_{2:L}(t)$. Moreover, the components evolve independently. If we call $(\hat{Z}_{2:L}(t))$ a fluid limit of $(\hat{N}_{2:L}(t))$, we can prove, as in [21, Prop 5.16 p125], that it satisfies

$$\hat{Z}_k(t) = (\hat{Z}_k(0) + (\lambda_k - \mu_k)t)_+, \quad \text{for } t \geq 0 \text{ and } 2 \leq k \leq L.$$

Moreover, by stochastic domination, we have $\bar{Z}_k(t) \leq \hat{Z}_k(t)$ for all $t \geq 0$ and $2 \leq k \leq L$. Since (m^i) satisfies Equation (49), we have that $\bar{Z}_k(0) = 0$, for $2 \leq k \leq L$ and we conclude that $\bar{Z}_k(t) = 0$ for all $t \geq 0$ and $2 \leq k \leq L$. □

We define $\bar{\mathbb{N}} = \mathbb{N} \cup \{+\infty\}$ and we consider $\bar{\mathbb{N}}^{K-2}$. We endow $\bar{\mathbb{N}}^{K-2}$ with the metric induced from the L_1-norm on $\mathbb{R}^{K-2}$ by the mapping $(x_2, \ldots, x_L) \mapsto (1/(x_2+1), \ldots, 1/(x_L+1))$. We can note that, in particular, $\bar{\mathbb{N}}^{K-2}$ is compact. In the same way as in [12], we then define a family of random measures on $[0, \infty) \times \bar{\mathbb{N}}^{K-2}$, for any $m \in \mathbb{N}^2$, any $\Gamma \subset \bar{\mathbb{N}}^{K-2}$ and $t \geq 0$,

$$\nu_m((0,t) \times \Gamma) = \int_0^t \mathbb{1}_{\{(N_2(\|m\|s), \ldots, N_L(\|m\|s)) \in \Gamma\}} \, \mathrm{d}s.$$

We then consider $\mathcal{L}_0(\bar{\mathbb{N}}^{K-2})$, the set of measures γ defined on $[0,t] \times \bar{\mathbb{N}}^{K-2}$ and such that $\gamma([0,t) \times \bar{\mathbb{N}}^{K-2}) = t$ for all $t \geq 0$. Under the topology induced by weak convergence on every compact and since $\bar{\mathbb{N}}^{K-2}$ is compact, $\mathcal{L}_0(\bar{\mathbb{N}}^{K-2})$ is compact. The next lemma shows that a random measure in $\mathcal{L}_0(\bar{\mathbb{N}}^{K-2})$ can be expressed as the sum of probability measures of $\bar{\mathbb{N}}^{K-2}$ indexed by s in $\mathbb{R}_+$.

Lemma 7. *We consider a sequence* $(m^i,\ i \in \mathbb{N})$ *satisfying Equation* (49)*. The set*

$$\left\{ ((\bar{N}(m^i, t)), \nu_{m^i}), i \in \mathbb{N} \right\}$$

is relatively compact. If $((\bar{Z}(t)), \nu)$ *is a limit process then there exists a process* ϑ *such that for all* t, $\vartheta(t, .)$ *is a random probability measure on* $\bar{\mathbb{N}}^{K-2}$ *and*

$$\forall t \geq 0,\ \forall \Gamma \subset \bar{\mathbb{N}}^{K-2},\ \nu([0,t) \times \Gamma) = \int_0^t \vartheta(s, \Gamma)\,\mathrm{d}s.$$

Proof. One can find a related result in a slightly different context in [14] and [12].

In order to prove the relative compactness of $\left\{((\bar{N}(m^i,t)), \nu_{m^i})\right\}$, we just need to prove that $\left\{(\bar{N}(m^i,t)), i \in \mathbb{N}\right\}$ and $\{\nu_{m^i}, i \in \mathbb{N}\}$ are relatively compact. We have already proved the relative compactness of the first one in lemma 5. $\mathcal{L}_0(\bar{\mathbb{N}}^{K-2})$ is compact then the second one is relatively compact.

We consider a convergent sequence $((\bar{N}(m^i,t)), \nu_{m^i})$ and its limit process $((\bar{Z}(t), \nu)$. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be the probability space on which they are defined. We call $\{\mathcal{F}_t\}$ the natural filtration of $((\bar{Z}(t), \nu)$.

We then define γ such that

$$\forall B \in \mathcal{F},\ \forall C \in \mathcal{B}([0,\infty)) \otimes \mathcal{B}(\bar{\mathbb{N}}^{K-2})\ \gamma(B \times C) = \mathbb{E}(\mathbb{1}_B \nu(C)).$$

According to [8, appendix 8], γ can be extended to a measure on $\mathcal{F} \otimes \mathcal{B}([0,\infty)) \otimes \mathcal{B}(\bar{\mathbb{N}}^{K-2})$ and there exists ϑ such that for all t, $\vartheta(t,.)$ is a random probability measure on $\bar{\mathbb{N}}^{K-2}$ and for any $B \in \mathcal{B}(\bar{\mathbb{N}}^{K-2})$, $(\vartheta(t,B), t \geq 0)$ is $\{\mathcal{F}_t\}$-adapted and for any $C \in \mathcal{F} \otimes \mathcal{B}([0,\infty))$,

$$\gamma(C \times B) = \mathbb{E}\left(\int_0^{+\infty} \mathbb{1}_C(s)\vartheta(s,B)\,\mathrm{d}s\right).$$

We define

$$M_B(t) = \nu([0,t] \times B) - \int_0^t \vartheta(s,B)\,\mathrm{d}s.$$

$((M_B(t))$ is $\{\mathcal{F}_t\}$-adapted and continuous. We consider $D \in \mathcal{F}_t$. We define $\mathbb{1}_C(\omega, s) = \mathbb{1}_D(\omega)\mathbb{1}_{[t,+\infty)}(s)$ and we have

$$\begin{aligned} \mathbb{E}\left(\mathbb{1}_D \nu([t,+\infty) \times B)\right) &= \gamma(C \times B), \\ &= \mathbb{E}\left(\mathbb{1}_D \int_t^{+\infty} \vartheta(s,B)\,\mathrm{d}s\right). \end{aligned}$$

It follows that

$$\mathbb{E}\left(\nu([t,+\infty) \times B) | \mathcal{F}_t\right) = \mathbb{E}\left(\int_t^{+\infty} \vartheta(s,B)\,\mathrm{d}s | \mathcal{F}_t\right).$$

Then, $(M_B(t))$ is a continuous $\{\mathcal{F}_t\}$-martingale. It has finite sample paths and then is almost surely identically null. Almost surely, the following equation holds for all t,

$$\forall B \subset \bar{\mathbb{N}}^{K-2},\ \nu([0,t) \times B) = \int_0^t \vartheta(s,B)\,\mathrm{d}s.$$

□

The previous lemma gives a convenient way to express the integral of linear combinations of indicator functions against a limit measure of (ν_m). We will use this technical lemma in the next one to characterize the limit of (ν_m). This is the most important part of the theorem and we exhibit the time scale separation between classes 0 and 1 and $2, \ldots, L$ here.

Proposition 6. *We consider a sequence* $(m^i,\ i\in\mathbb{N})$ *satisfying Equation* (49) *and such that* $((\bar{N}(m^i,t)),\nu_{m^i})$ *is a converging sequence and* h *a continuous function on* $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$*. Then, we have that*

$$\left(\int_0^t h(\bar{N}_0(m^i,s),\bar{N}_1(m^i,s),N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\,\mathrm{d}s\right)$$

converges in distribution to

$$\left(\int_0^t \sum_{y\in\bar{\mathbb{N}}^{K-2}} h\left(\bar{Z}_0(s),\bar{Z}_1(s),y\right)\tilde{\pi}^{\alpha(s)}(y)\,\mathrm{d}s\right)$$

with

$$\forall t\in\mathbb{R}_+,\ \alpha(t)=\frac{\bar{Z}_0(t)}{\bar{Z}_0(t)+\bar{Z}_1(t)}$$

and where, $\tilde{\pi}^{\alpha(t)}$ *is the stationary distribution of the process* $(\tilde{N}_{2:L}^{\alpha(t)}(s))$ *defined in Section 3.3.*

In particular, the function

$$(x_0,x_1,n_2,\dots,n_L)\mapsto\psi_0(x_0,x_1,n_2a_2,\dots,n_La_L)$$

is continuous on $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$ *and*

$$\left(\int_0^t \phi_0(\bar{N}_0(m^i,s),\bar{N}_1(m^i,s),N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\,\mathrm{d}s\right)$$

converges in distribution to

$$\left(\int_0^t \bar{\phi}_0\left(\alpha(s)\right)\mathrm{d}s\right)$$

Proof. The functions which are continuous on $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$ for the topology induced by the natural topology on $[0,1]^2$ and the topology induced by the mapping $(x_2,\dots,x_L)\mapsto(1/(x_2+1),\dots,1/(x_L+1))$ are the bounded functions h which are continuous on $[0,1]^2\times\mathbb{N}^{K-2}$ for the natural topology and such that for each $x\in[0,1]^2$, $y\mapsto h(x,y)$ admits a unique limit $h(x,\infty)$ in all directions such that $\|y\|\to\infty$ and the function $x\mapsto h(x,\infty)$ has to be continuous on $[0,1]^2$. We can remark that, for all $(x_0,x_1)\in[0,1]^2$ $\psi_0(x_0,x_1,n_{2:L}\odot a_{2:L})\to 0$ when $\|n_{2:L}\|\to+\infty$ and the function

$$(x_0,x_1,n_2,\dots,n_L)\mapsto\psi_0(x_0,x_1,n_2a_2,\dots,n_La_L)$$

is then continuous on $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$.

We consider h a continuous function on $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$, since the space $[0,1]^2\times\bar{\mathbb{N}}^{K-2}$ is compact, Lemma 7 implies directly that

$$\left(\int_0^t h(\bar{N}_0(m^i,s),\bar{N}_1(m^i,s),N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\,\mathrm{d}s\right)$$

converges in distribution to

$$\left(\int_0^t \sum_{y\in\bar{\mathbb{N}}^{K-2}} h\left(\bar{Z}_0(s),\bar{Z}_1(s),y\right)\vartheta(s,y)\,\mathrm{d}s\right).$$

We are now able to fully characterize the random measures $(\vartheta(.,t))$. For any continuous bounded function f on $\bar{\mathbb{N}}^{K-2}$ and any $m\in\mathbb{N}^{K-2}$, we define,

$$\begin{aligned}\bar{M}_f(m,t)=\frac{1}{\|m\|}&\Big(f(N_2(\|m\|t),\dots,N_L(\|m\|t))-f(0)\Big)\\&-\sum_{k=2}^{L}\lambda_k\int_0^t\Big(f((N_2(\|m\|s),\dots,N_L(\|m\|s))+e_k)-f(N_2(\|m\|s),\dots,N_L(\|m\|s))\Big)\,\mathrm{d}s\\&-\sum_{k=2}^{L}\mu_k\int_0^t\Big(\big(f((N_2(\|m\|s),\dots,N_L(\|m\|s))-e_k)-f(N_2(\|m\|s),\dots,N_L(\|m\|s))\big)\\&\qquad\qquad\phi_k(\bar{N}_0(m,s),\bar{N}_1(m,s),N_2(\|m\|s),\dots,N_L(\|m\|s))\Big)\,\mathrm{d}s.\end{aligned}$$

As $(\bar{M}(m,t))$ defined by equation (50) is a martingale, $(\bar{M}_f(m,t))$ is a martingale. We consider a convergent sequence $((\bar{N}(m^i,t)),\nu_{m^i})$. We have that $(\bar{M}_f(m^i,t))$ converges in distribution to 0. $\|m^i\|^{-1}(f(N_2(\|m^i\|t),\dots,N_L(\|m^i\|t))-f(0))$ also converges to 0 because f is bounded. As a consequence, the following term

$$\begin{aligned}&\sum_{k=2}^{L}\lambda_k\int_0^t\Big(f((N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))+e_k)-f(N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\Big)\,\mathrm{d}s\\&-\sum_{k=2}^{L}\mu_k\int_0^t\Big(\big(f((N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))-e_k)-f(N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\big)\\&\qquad\qquad\phi_k(\bar{N}_0(m^i,s),\bar{N}_1(m^i,s),N_2(\|m^i\|s),\dots,N_L(\|m^i\|s))\Big)\,\mathrm{d}s\end{aligned}$$

also converges in distribution to 0. But, by the continuous mapping theorem and Lemma 7, it converges in distribution to

$$\begin{aligned}\int_0^t\sum_{k=2}^{L}\Bigg(&\lambda_k\sum_{y\in\bar{\mathbb{N}}^{K-2}}f(y+e_k)-f(y)\\&+\mu_k\sum_{y\in\bar{\mathbb{N}}^{K-2}}(f(y-e_k)-f(y))\varphi_k(\bar{Z}_0(s),\bar{Z}_1(s),y)\Bigg)\vartheta(s,y)\,\mathrm{d}s.\end{aligned}$$

Consequently, this is null almost surely for all t and we have then, for Lebesgue-almost every t,

$$\begin{aligned}\sum_{k=2}^{L}\Bigg(&\lambda_k\sum_{y\in\bar{\mathbb{N}}^{K-2}}f(y+e_k)-f(y)+\\&\mu_k\sum_{y\in\bar{\mathbb{N}}^{K-2}}(f(y-e_k)-f(y))\varphi_k(\bar{Z}_0(t),\bar{Z}_1(t),y)\Bigg)\vartheta(t,y)=0.\end{aligned}$$

We deduce immediately that

$$\int_{\bar{\mathbb{N}}^{K-2}}\tilde{\Omega}^{\alpha(t)}(f)(y)\vartheta(t,\mathrm{d}y)=0$$

where $\alpha(t)=\bar{Z}_0(t)/(\bar{Z}_0(t)+\bar{Z}_1(t))$ and $\tilde{\Omega}^{\alpha(t)}$ is the infinitesimal generator of $(\tilde{N}^{\alpha(t)}_{2:L}(s))$, defined in Section 3.3. This proves exactly that $\vartheta(t,.)$ is invariant for

$(\tilde{N}^{\alpha(t)}_{2:L}(s))$. By uniqueness of the invariant distribution of such a process, we have that

$$\vartheta(t,.) = \tilde{\pi}^{\alpha(t)}.$$
